1 Abstract

VSEPR-SIM is a deterministic atomistic formation kernel that converts elemental composition and thermodynamic boundary conditions into physically consistent three-dimensional atomic configurations. Most atomistic simulation workflows begin with an assumed initial structure and focus on time evolution through molecular dynamics or energy minimisation. The problem of generating that initial structure from composition alone — the *formation problem* — is substantially harder: it requires simultaneous geometry construction, topology inference, and energy evaluation, all under a deterministic contract that guarantees bit-identical reproducibility.

This work presents the architecture, physical model, and verification methodology of the VSEPR-SIM v2.7.1 kernel. The engine combines Lennard–Jones van der Waals interactions, Coulomb electrostatics with dielectric screening, harmonic bonded terms, and deterministic structural optimisation (FIRE) alongside velocity-Verlet integration for dynamical validation. The modular architecture separates the formation kernel from downstream consumers through a pure-function model interface and a three-layer bridge, enabling the kernel to serve as a reproducible computational substrate for molecular dynamics initialisation, crystal exploration, and candidate generation for electronic-structure methods.

A comprehensive verification framework accompanies the kernel. The deep verification suite evaluates analytic force–energy consistency, electrostatic scaling behaviour, crystal geometry fidelity, molecular bond detection, dielectric screening, and numerical stability across a wide range of systems. In total, 485 verification checks, including 256 deep-suite tests, pass without failure or skip.

By establishing a verified deterministic formation kernel, VSEPR-SIM provides a reproducible computational substrate for downstream modelling workflows. The primary contribution is not another simulation engine, but a *foundational layer in the modelling stack*: a reliable formation interface between compositional chemistry and atomistic simulation.

2 Project Motivation

Atomistic simulation has become a central tool in chemistry, materials science, and condensed-matter physics. Modern molecular simulation frameworks enable detailed modelling of molecular dynamics, thermodynamic ensembles, and large-scale materials behaviour. However, many simulation workflows implicitly assume that a plausible structural configuration is already known. Initial coordinates are typically taken from experimental databases, prior calculations, or heuristic construction tools, and the simulation then focuses on relaxation or dynamical evolution of that structure.

The problem of structure formation from composition, however, is substantially more difficult. A formation engine must generate candidate geometries, evaluate their physical plausibility, and converge toward stable configurations without relying on an externally provided structural template. In such systems, errors in the underlying physics kernel can propagate silently: incorrect force expressions, inconsistent energy derivatives, or unstable numerical integration may produce structures that appear chemically plausible while being physically inconsistent. Because atomistic simulations are highly nonlinear, these errors are often difficult to detect through inspection of individual results.

VSEPR-SIM addresses this challenge through two design principles.

The first is deterministic kernel design. Given identical inputs, the engine produces bit-identical outputs. All stochastic elements are explicitly seeded and recorded, enabling exact reproduction of simulation results across runs and platforms.

The second is verification-driven development. Each physical subsystem is accompanied by a self-contained verification suite that evaluates analytic correctness, empirical consistency, and numerical

stability. Verification tests cover force–energy consistency, electrostatic scaling, crystal geometry generation, molecular bond detection, dielectric screening behaviour, and energy conservation under dynamical integration.

Together, these principles establish a development framework in which physical modelling, numerical algorithms, and software architecture are continuously validated against empirical references and analytic expectations. The resulting kernel provides a stable and reproducible foundation for exploring deterministic approaches to molecular and crystalline structure formation.

2.1 Formation Kernels as Computational Infrastructure

Most atomistic workflows begin with an initial-structure problem. Molecular dynamics requires starting coordinates; density-functional theory requires an input geometry; crystal simulations require lattice seeds; screening pipelines require candidate structures. In each case the practitioner must supply a physically plausible atomic configuration before any downstream calculation can begin. Many tools simply assume this structure is already known.

A formation kernel addresses the missing step: converting a compositional specification and a set of environmental constraints into a valid atomic configuration. When that kernel is deterministic and verified, it becomes reusable infrastructure — a computational interface between compositional chemistry and downstream modelling.

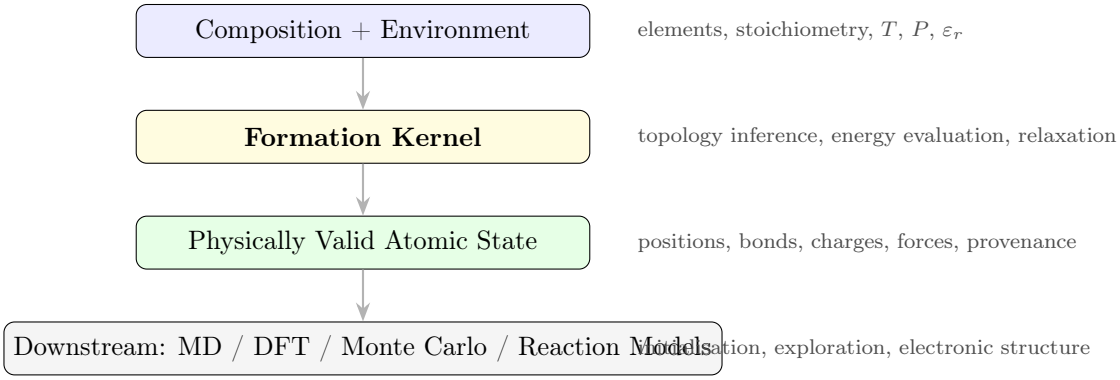

Figure 1: The formation kernel as computational infrastructure. Downstream systems consume the generated atomic state without knowledge of how it was produced.

This framing has two consequences for the present work. First, the kernel interface must be minimal and deterministic: given the same composition and environment, it must produce the same atomic configuration. Second, because the kernel is foundational, its analytic and numerical correctness must be established before any downstream system can trust its output. These requirements motivate both the pure-function architecture (Section 4) and the verification framework (Section 8).

2.2 Silent Failure Modes in Atomistic Simulation

Atomistic simulation engines fail silently when any of several internal consistency conditions are violated. In particular:

1. **Force–energy divergence.** The analytic gradient of the potential energy with respect to atomic positions must equal the negative of the force vector. Inconsistency between these quantities — arising from algebraic errors, missing derivative terms, or numerical truncation —

produces a system where forces drive atoms in directions that do not correspond to energy descent. Such errors can produce plausible-looking trajectories with incorrect energetics.

2. **Geometric emitter errors.** Crystal and molecular structure generators must produce geometries with the correct atom count, symmetry, nearest-neighbour distances, and coordination numbers. Errors in unit cell construction, fractional coordinate placement, or supercell replication can introduce structural defects that propagate through subsequent calculations without producing obvious diagnostic signals.

3. **Electrostatic scaling breakdown.** The Coulomb interaction must scale correctly with the dielectric constant of the medium. An implementation error that applies screening to only one of the energy or force expressions, or that neglects to scale the switching function consistently, produces a system where energy and force no longer correspond to the same physical model.

4. **Numerical drift.** Symplectic integrators conserve a shadow Hamiltonian that is close to, but not identical to, the true Hamiltonian. If the integration loop introduces systematic errors — for example, by applying unit conversions inconsistently between the half-step velocity update and the full-step position update — the total energy will drift monotonically, violating the fundamental conservation law of the NVE ensemble.

5. **Parameter table incompleteness.** Force-field parameter tables that silently fall back to default values for undefined element types produce simulations that use incorrect physics without warning. A system that evaluates gold atoms using carbon parameters will produce finite, plausible-looking numbers, but those numbers have no physical meaning.

These failure modes are difficult to detect through normal use because each individual simulation may produce a structurally reasonable result. The verification framework described in this paper is designed to detect each of these failure classes systematically.

2.3 The Formation Problem

The central scientific problem addressed by VSEPR-SIM is *deterministic structure formation*: given a set of elements, stoichiometry, and thermodynamic boundary conditions, generate a physically plausible three-dimensional structure.

This problem differs from conventional molecular dynamics or Monte Carlo simulation in several ways:

Aspect	**Conventional MD**	**Formation Engine**
Starting point	Known structure	Composition only
Primary goal	Time evolution	Structure prediction
Success criterion	Trajectory accuracy	Structural plausibility
Initial coordinates	From database	Must be generated
Topology	Given or fixed	Must be inferred
Reproducibility	Desirable	Required by design

In a formation context, the engine must solve two coupled problems simultaneously: determine where atoms should be placed in space, and evaluate whether the resulting configuration is energetically favourable. Errors in either stage corrupt the other, creating a feedback loop that can converge to physically meaningless structures if the underlying kernel is not rigorously verified.

The design philosophy of VSEPR-SIM is therefore that formation physics requires deterministic kernels, and deterministic kernels require verification-driven development. The verification results presented in this paper demonstrate that the kernel satisfies these requirements across its current scope of physical coverage.

3 Historical Development

The development of VSEPR-SIM proceeded through several architectural phases, each motivated by specific limitations encountered in earlier versions of the engine. The progression from v2.5 to v2.7 reflects a deliberate arc: establish the formation methodology, explore generative models, diagnose and stabilise the kernel, and verify the result exhaustively. Each phase was motivated by specific limitations encountered in the previous one.

Table 1: Development phases and their architectural lessons.

Phase	**Version**	**Purpose and Key Outcome**
Methodology	v2.5	Establish the formation pipeline: topology generation, classical force-field evaluation, numerical relaxation.
Reaction control	v2.5.3	Heat-gated reaction pathways under thermal conditions; revealed early kernel instabilities.
Generative	v2.6.1	Aggressive formation-space search; exposed convergence plateaus at shallow saddle points.
Diagnostics	v2.6.2	Root-cause analysis: f-block degeneracy, metric mismatch, coordinate-descent artefacts, smoothness penalties.
Stabilisation	v2.6.3	Compile-time empirical parameter database (UFF, bond lengths, crystal references); eliminated parameter ambiguity.
Architecture	v2.7.0	Three-layer Qt6 desktop bridge; separated kernel from UI, ensuring computational independence.
Verification	**v2.7.1**	**Deep verification milestone (485/485 PASS); kernel transitions from research software to verified infrastructure.**

The critical turning point was the v2.6.2 plateau investigation. The failure modes observed during generative exploration — optimiser deadlocks, parameter fallback errors, force–energy inconsistencies visible only under stress — motivated a shift from generative experimentation toward verification-driven kernel development. This shift now forms the architectural foundation of the system: the kernel must be trustworthy before any formation workflow can produce meaningful results.

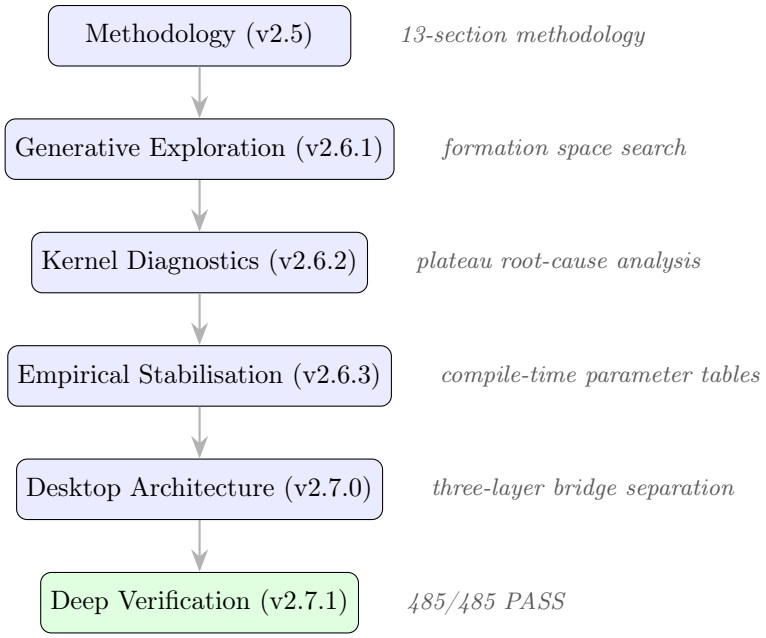

Figure 2: Development arc from methodology formulation through deep verification milestone.

4 System Architecture

The VSEPR-SIM formation engine is organised around a layered architecture in which each layer has a single, well-defined responsibility. No layer accesses the internal data structures of another; all communication passes through the canonical state representation. This section describes the pipeline, the state representation, the model interface, the three-layer bridge, and the explicit kernel boundary that separates formation physics from downstream consumers.

4.1 Formation Kernel Boundary

The formation kernel defines the minimal deterministic interface that converts compositional information and environmental constraints into physically valid atomic configurations. Its responsibility is precisely:

$$\text{composition} + \text{environment} \longrightarrow \text{atomic configuration}$$

Everything outside this boundary — visualisation, batch workflows, campaign orchestration, electronic-structure coupling — is a downstream consumer. The kernel does not know whether its output will be used for molecular dynamics initialisation, DFT geometry input, or interactive display. This separation ensures that the kernel can be independently verified, optimised, or replaced without affecting any higher-level system.

4.2 Formation Pipeline

The engine processes structures through a six-layer pipeline. Each layer transforms or validates the state before passing it to the next:

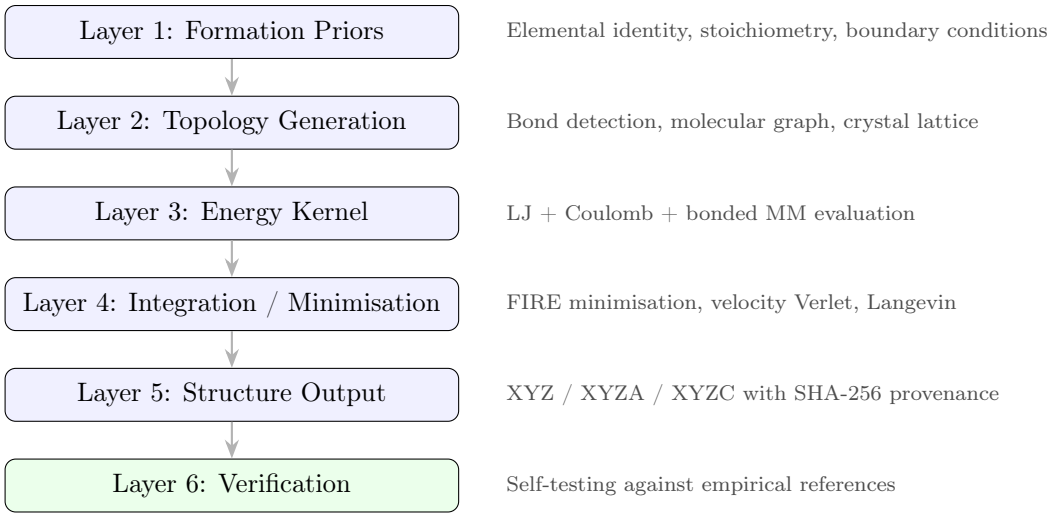

Figure 3: The six-layer formation pipeline. Each layer operates on the canonical State and passes the result downstream.

Layer 1 (Formation Priors) establishes the initial conditions for structure generation. This includes elemental composition, stoichiometry, crystal preset selection, and thermodynamic boundary conditions such as temperature, pressure, and medium type. The output of this layer is a specification that uniquely determines the structure generation task.

Layer 2 (Topology Generation) constructs the initial atomic geometry. For molecules, this involves placing atoms according to VSEPR geometry rules and inferring bond topology from covalent radii. For crystals, this involves selecting a unit cell preset, placing basis atoms at fractional coordinates, and replicating the cell to form a supercell. The topology generation step produces a fully populated `State` object with positions, types, masses, charges, and (where applicable) bond connectivity.

Layer 3 (Energy Kernel) evaluates the potential energy and forces for the current configuration. The kernel supports multiple interaction models — Lennard–Jones van der Waals, Coulomb electrostatics, harmonic bonds, harmonic angles, and periodic torsions — which can be composed additively through the `CompositeModel` interface. Each model writes to the energy ledger and force arrays independently.

Layer 4 (Integration / Minimisation) evolves the structure toward a lower-energy configuration. Three algorithms are available: FIRE for energy minimisation, velocity Verlet for NVE dynamics, and Langevin integration for NVT sampling. Each algorithm operates directly on the `State` object, modifying positions, velocities, and forces in place.

Layer 5 (Structure Output) serialises the final structure to disk in XYZ-family formats with metadata annotations and SHA-256 provenance hashes.

Layer 6 (Verification) executes the automated self-testing suites that validate the kernel against empirical references, analytic identities, and numerical stability criteria.

4.3 The Canonical Simulation State

The computational layer operates on a single data structure that represents the complete instantaneous configuration of an N-particle system. This structure, defined in `atomistic/core/state.hpp`, is the canonical representation through which all layers communicate:

```
struct State {
    uint32_t N{};
```

```
    std::vector<Vec3>     X;      // positions      (N, Angstrom)
    std::vector<Vec3>     V;      // velocities     (N, Ang/fs)
    std::vector<double>   T;      // per-particle temperature proxy
    std::vector<double>   Q;      // charges        (N, elementary charge)
    std::vector<double>   M;      // masses         (N, amu)
    std::vector<uint32_t> type;   // species id     (N, atomic number Z)

    std::vector<Edge>     B;      // bond topology  (graph edges)
    std::vector<Event>    L;      // event log

    std::vector<Vec3>     F;      // forces         (N, kcal/mol/Ang)
    EnergyTerms           E{};    // energy ledger

    BoxPBC                box;    // periodic boundary conditions
};
```

Formally, the state at time t is the tuple:

$$\mathcal{S}(t) = \big(N,\ \mathbf{M},\ \boldsymbol{\tau},\ \mathbf{X}(t),\ \mathbf{V}(t),\ \mathbf{Q}(t),\ \mathbf{B}(t),\ \mathbf{F}(t),\ \mathcal{E}(t),\ \mathcal{L},\ \mathcal{B}\big) \tag{1}$$

where $\mathcal{B}$ encodes the periodic simulation cell via its three edge lengths (L_x, L_y, L_z) and the minimum-image displacement rule:

$$\Delta\mathbf{r}_{ij}^{\mathrm{MIC}} = \Delta\mathbf{r}_{ij} - \mathbf{L}\cdot\mathrm{round}\left(\frac{\Delta\mathbf{r}_{ij}}{\mathbf{L}}\right) \quad \text{(component-wise)} \tag{2}$$

The energy ledger decomposes the total potential energy into additive terms:

$$\mathcal{E} = \{U_{\mathrm{bond}},\ U_{\mathrm{angle}},\ U_{\mathrm{tors}},\ U_{\mathrm{vdW}},\ U_{\mathrm{Coul}},\ U_{\mathrm{ext}},\ U_{\mathrm{pol}}\} \tag{3}$$

The `EnergyTerms` structure carries this decomposition through every layer, enabling per-term diagnostics and verification at any point in the pipeline.

4.3.1 State Invariant

A sanity check function enforces a minimal consistency condition on any State before it is passed to a kernel operation:

```
inline bool sane(const State& s) {
    if (s.N == 0) return false;
    if (s.X.size() != s.N || s.V.size() != s.N ||
        s.Q.size() != s.N || s.M.size() != s.N ||
        s.type.size() != s.N) return false;
    return true;
}
```

All parallel arrays must have length N, and $N = 0$ is treated as an invalid state. Any kernel operation that receives an invalid state raises an exception before computation begins. This early-rejection pattern prevents downstream corruption from malformed inputs.

4.3.2 Design Rationale: Parallel Arrays

The State uses parallel arrays rather than an array-of-structures layout. This choice optimises for cache locality during force evaluation, where the inner loop iterates over all particle pairs and

accesses only positions and type indices. The velocity and charge arrays are accessed only during integration steps, which occur at a lower frequency than force evaluation.

The bond topology is stored as a flat edge list (`std::vector<Edge>`) rather than an adjacency matrix, which is more memory-efficient for sparse molecular graphs and allows $O(|B|)$ iteration during bonded-pair exclusion construction.

4.4 Model Interface

All force models implement a pure-function contract:

$$\texttt{eval} : \mathcal{S} \times \Theta \longrightarrow (\mathbf{F}, \mathcal{E}) \tag{4}$$

where Θ is the parameter set containing the cutoff radius r_c, Coulomb constant k_e, and environment context (medium type, dielectric constant, temperature, pressure). The interface is defined as:

```
struct ModelParams {
    double rc    = 10.0;       // cutoff radius (Ang)
    double k_coul = 332.0636;  // Coulomb constant (kcal*Ang/(mol*e^2))
    EnvironmentContext env;     // physical context
};

struct IModel {
    virtual ~IModel() = default;
    virtual void eval(State& s, const ModelParams& p) const = 0;
};
```

This is a pure function in the sense that given the same `State` and `ModelParams`, it always produces the same forces and energies. The model does not store mutable state between calls, does not access global variables, and does not depend on call order. These properties are verified by the determinism checks in Phase 1 of the verification suite.

4.5 Composite Model Architecture

The engine supports arbitrary composition of force models through the `CompositeModel` class, which implements `IModel` by evaluating a collection of sub-models and summing their contributions:

```
class CompositeModel : public IModel {
    void eval(State& s, const ModelParams& p) const override {
        std::fill(s.F.begin(), s.F.end(), Vec3{0, 0, 0});
        s.E = {};
        for (const auto& m : models_) {
            State tmp = s;
            tmp.F.assign(s.N, {0,0,0});
            tmp.E = {};
            m->eval(tmp, p);
            for (uint32_t i = 0; i < s.N; ++i)
                s.F[i] = s.F[i] + tmp.F[i];
            s.E.Ubond  += tmp.E.Ubond;
            s.E.Uangle += tmp.E.Uangle;
            // ... (all seven ledger terms)
        }
    }
```

```
};
```

The default composition for molecular systems is:

1. **Bonded model**: harmonic bonds, harmonic angles, periodic torsions (from inferred topology)
2. **Nonbonded model**: LJ 12-6 + Coulomb with 1-2 exclusions, quintic switching, and dielectric screening

The bonded model is constructed automatically from the bond topology in `State::B`. Angles are inferred from pairs of bonds sharing a common vertex; dihedrals from chains of three consecutive bonds. This automatic topology inference allows the composite model to be constructed from any `State` without requiring an external topology file.

4.6 Environment Context

Atomic structures generated from identical compositions may differ substantially depending on environmental conditions. A molecule relaxed in vacuum adopts a different equilibrium geometry than the same molecule in aqueous solution, because dielectric screening reduces Coulomb interactions by a factor of $\varepsilon_r \approx 78$. Similarly, a crystal under high pressure may prefer a denser polymorph than the same composition at ambient conditions. Explicit encoding of environmental context is therefore not an implementation convenience but a physical modelling decision: it allows the formation kernel to generate configurations that are consistent with the surrounding physical environment.

The `EnvironmentContext` structure encodes:

Field	Type	Physical Meaning
`medium`	enum	Gas phase, dry condensed, or solution
`temperature`	K	Thermodynamic temperature
`pressure`	atm	Mechanical pressure
`dielectric`	—	Relative permittivity ε_r
`ionic_strength`	mol/L	Ionic concentration (for Debye screening)
`periodic`	bool	Whether PBC is active

Three medium classes are defined:

- **NearVacuum** ($\varepsilon_r \approx 1.0$): gas-phase or isolated cluster. Coulomb unscreened.
- **DryCondensed** ($\varepsilon_r = 2$–5): bulk solid, thin film, dry powder. Packing and sterics dominate.
- **Solution** ($\varepsilon_r \gg 1$): aqueous or polar solvent. Coulomb screened by $1/\varepsilon_r$.

The Coulomb scaling factor is derived directly from the dielectric constant:

$$k_{\text{eff}} = \frac{k_e}{\varepsilon_r} \tag{5}$$

This scaling is applied uniformly to both the energy and force expressions, ensuring consistency between them. The verification suite (Suite H, Suite K) validates this scaling across 19 experimental solvents from the CRC Handbook, 104th Edition.

4.7 Three-Layer Desktop Architecture

The v2.7.0 release introduced a Qt6 desktop application that provides interactive access to the formation engine. The application is structured as a strict three-layer architecture:

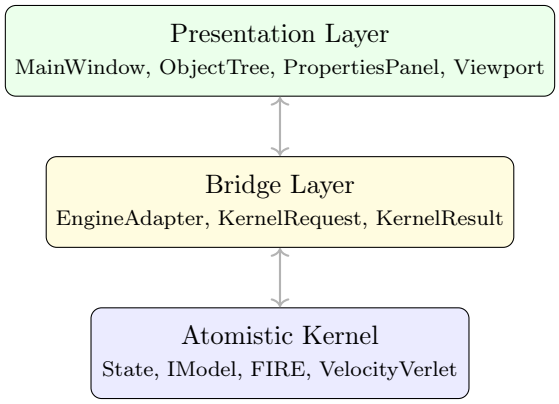

Figure 4: Three-layer desktop architecture. The bridge layer ensures the atomistic kernel remains independent of the GUI framework.

The bridge layer provides a single entry point for all kernel operations:

```
enum class KernelOp {
    LoadXYZ, SaveXYZ, Relax, MD_NVE, MD_NVT,
    SinglePoint, InferBonds, EmitCrystal
};

struct KernelRequest {
    KernelOp op;
    std::string file_path;
    int max_steps = 1000;
    double dt = 1.0;
    double temperature = 300.0;
    EnvironmentContext env;
    // ...
};

class EngineAdapter {
    KernelResult run(const KernelRequest& req, ProgressFn progress = nullptr);
};
```

This design enforces a strict invariant: the desktop application never instantiates `State`, `IModel`, or any other atomistic type directly. All interactions pass through `KernelRequest` and `KernelResult`. This means the computational kernel can be modified, optimised, or replaced without any change to the user interface code.

4.8 Physics Status Registry

An unusual feature of the VSEPR-SIM architecture is the *physics status registry*, a compile-time data structure that records the operational state of every physics term in the system:

```
enum class PhysicsState {
```

```
    ACTIVE,      // implemented, evaluated, passes verification
    PARTIAL,     // interface exists, logic incomplete
    DEFERRED,    // interface intact, eval contribution = 0
    ABSENT       // not yet started
};

inline constexpr PhysicsTerm PHYSICS_REGISTRY[] = {
    {"LJ␣12-6␣nonbonded",    PhysicsState::ACTIVE, "UFF␣parameters..."},
    {"Harmonic␣bonds",        PhysicsState::ACTIVE, "BondedModel..."},
    {"Harmonic␣angles",       PhysicsState::ACTIVE, "BondedModel..."},
    {"Periodic␣torsions",     PhysicsState::PARTIAL, "implemented,␣not␣composed"},
    {"Coulomb␣electrostatics",PhysicsState::ACTIVE, "with␣dielectric␣screening"},
    {"Dipole␣interactions",   PhysicsState::PARTIAL, "SCF␣solver␣implemented"},
    // ...
};
```

This registry is version-controlled alongside the source code. It serves three functions:

1. **Documentation**: any reader of the codebase can determine at a glance which physics terms are active, which are incomplete, and which are deliberately deferred.
2. **Verification targeting**: the phase verification executables query the registry to determine which terms should be tested.
3. **Honesty enforcement**: the registry must be updated whenever a physics term changes state. A mismatch between the registry and the actual evaluation code is treated as a verification failure.

5 Energy Model

The total potential energy of the system is the sum of independently computed terms:

$$U_{\text{total}} = U_{\text{bond}} + U_{\text{angle}} + U_{\text{tors}} + U_{\text{LJ}} + U_{\text{Coul}} + U_{\text{ext}} + U_{\text{pol}} \tag{6}$$

Each term is stored in the energy ledger and can be inspected independently at any point during a simulation.

The current verification scope focuses on the terms required to validate core kernel behaviour: nonbonded interactions (LJ, Coulomb), bonded topology (harmonic bonds and angles), electrostatic screening (dielectric), and numerical stability (FIRE, Verlet). These terms are sufficient to establish the deterministic baseline. Higher-order interactions — torsional barriers, dipole polarisation, and charge equilibration — are implemented (see the physics registry in Section 4.8) and will be incorporated into the default evaluation chain as verification coverage expands. This scope is intentional, not incomplete: each physics term enters the active chain only after its force–energy consistency has been independently verified.

The following subsections describe each active term, its functional form, its parameter source, and its verification coverage.

5.1 Lennard–Jones 12-6 Potential

Pairwise van der Waals interactions are modelled by the Lennard–Jones 12-6 potential:

$$U_{\text{LJ}}(r_{ij}) = 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] \tag{7}$$

The potential has a minimum at $r_{\min} = 2^{1/6}\sigma$ with well depth $-\varepsilon$.

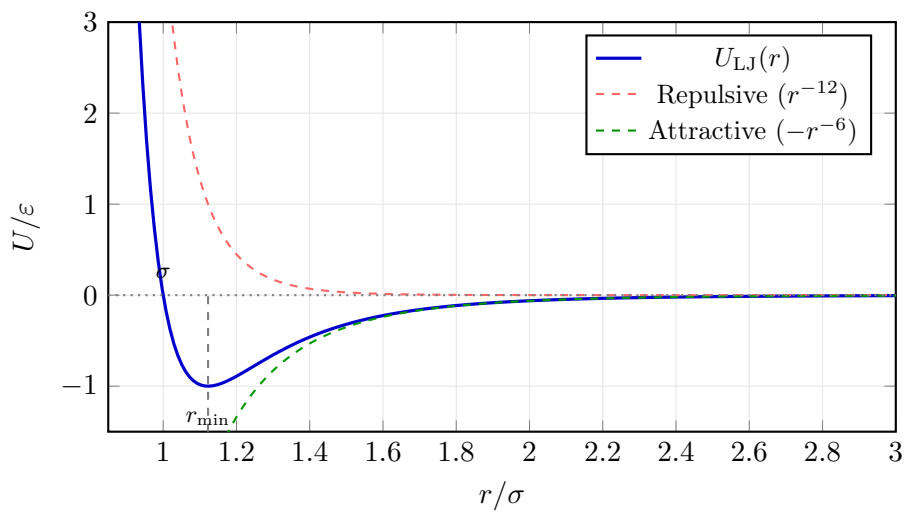

Figure 5: The Lennard–Jones 12-6 potential, showing the repulsive r^{-12} and attractive $-r^{-6}$ contributions. The equilibrium distance $r_{\min} = 2^{1/6}\sigma$ and well depth ε are marked.

5.1.1 Parameter Source

Parameters are drawn from the Universal Force Field (UFF) of Rappé et al. (1992). The v2.7.1 database includes 42 elements with verified σ and ε values, loaded at compile time from `src/pot/uff_params.hpp`. For elements not in the UFF table, a carbon-like fallback ($\sigma = 3.851$ Å, $\varepsilon = 0.105$ kcal/mol) is used and logged as a warning.

5.1.2 Combining Rules

Heteronuclear pair parameters are computed using Lorentz–Berthelot mixing rules:

$$\sigma_{ij} = \frac{\sigma_i + \sigma_j}{2} \qquad \text{(arithmetic mean)} \tag{8}$$

$$\varepsilon_{ij} = \sqrt{\varepsilon_i \cdot \varepsilon_j} \qquad \text{(geometric mean)} \tag{9}$$

5.1.3 Cutoff and Switching Function

The LJ potential is truncated at the cutoff radius r_c (default 10 Å) with a quintic switching function that smoothly reduces the interaction to zero over the interval $[0.9\,r_c,\ r_c]$:

$$S(x) = 1 - 10x^3 + 15x^4 - 6x^5 \qquad \text{where } x = \frac{r - r_{\mathrm{on}}}{r_c - r_{\mathrm{on}}} \in [0, 1] \tag{10}$$

The switching function derivative is:

$$S'(x) = -30x^2(1 - 2x + x^2) \cdot \frac{1}{r_c - r_{\mathrm{on}}} \tag{11}$$

Both the energy and force expressions are multiplied by S, and the force receives an additional contribution from S' to maintain consistency:

$$F_{\mathrm{total}}(r) = (F_{\mathrm{LJ}}(r) + F_{\mathrm{Coul}}(r)) \cdot S(r) + (U_{\mathrm{LJ}}(r) + U_{\mathrm{Coul}}(r)) \cdot S'(r) \tag{12}$$

This ensures that the force is the exact negative gradient of the switched energy at all distances, preventing force–energy inconsistency at the cutoff boundary. Suite B verifies this smoothness property by scanning the energy curve across the switching region and checking for discontinuities.

5.1.4 1-2 Exclusions

Bonded atom pairs (connected by a single bond in the topology graph) are excluded from nonbonded evaluation. At covalent bond distances ($r \approx 0.7$–1.1 Å), atoms are deep inside the LJ repulsive wall ($r \ll \sigma$), producing unphysical energies of 10^5–10^6 kcal/mol. The exclusion list is built from `State::B` before the pairwise loop begins, using a hash set keyed by atom index pairs.

This exclusion mechanism was introduced in v2.7.1 after the Phase 2 verification identified bonded-pair LJ repulsion as a dominant source of error in molecular energetics. The discovery and correction process is documented in the Phase 2 revalidation report.

5.2 Coulomb Electrostatics

Point-charge electrostatics with distance-dependent dielectric screening:

$$U_{\text{Coul}}(r_{ij}) = \frac{k_e\, q_i\, q_j}{\varepsilon_r\, r_{ij}} \tag{13}$$

where $k_e = 332.0636$ kcal/mol · Å/e^2 is the Coulomb constant in AMBER units, and ε_r is the relative dielectric constant drawn from the `EnvironmentContext`.

The force expression is:

$$F_{\text{Coul}}(r_{ij}) = \frac{k_e\, q_i\, q_j}{\varepsilon_r\, r_{ij}^2} \tag{14}$$

The Coulomb interaction uses the same quintic switching function as the LJ term, ensuring smooth truncation at the cutoff radius.

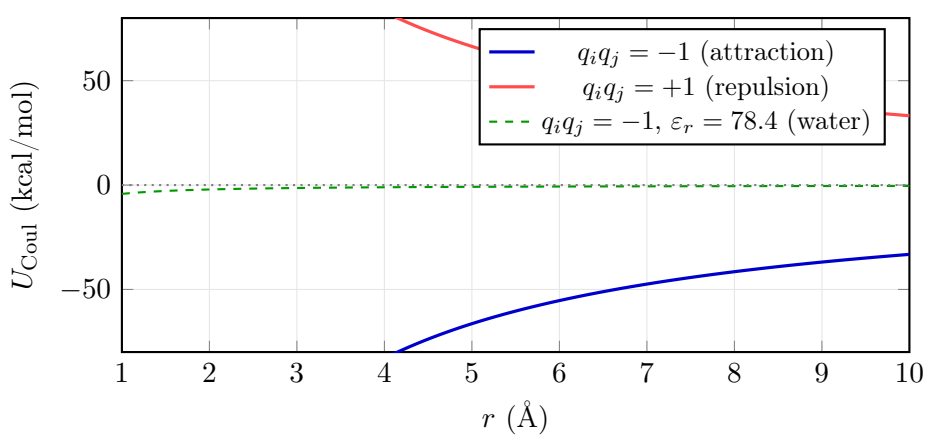

Figure 6: Coulomb potential for unit charges in vacuum and in water ($\varepsilon_r = 78.4$). Dielectric screening reduces the interaction strength by a factor of ε_r.

5.2.1 Dielectric Screening Validation

The dielectric model supports near-vacuum ($\varepsilon_r = 1.0$) for gas-phase systems and explicit solvent dielectrics from the CRC Handbook, 104th Edition. Verification Suite H evaluates 19 solvents ranging from hexane ($\varepsilon_r = 1.88$) to water ($\varepsilon_r = 78.4$), confirming that the ratio $U_{\text{vac}}/U_\varepsilon$ equals ε_r

to within 10^{-6} relative error for each solvent. Suite K extends this with randomised distance and charge samples.

5.3 Harmonic Bond Stretch

Covalent bonds are modelled by a harmonic potential:

$$U_{\text{bond}} = k_b(r - r_0)^2 \tag{15}$$

where k_b is the force constant (kcal/mol/Å^2) and r_0 is the equilibrium bond length (Å). The force is:

$$\mathbf{F}_i = -2k_b(r - r_0)\hat{\mathbf{r}}_{ij} \tag{16}$$

Bond parameters are assigned automatically from the topology graph using generic values derived from the element pair. Tight molecular convergence requires matched force-field parameters from a complete parameterisation (AMBER, CHARMM, or UFF valence); the current implementation uses generic estimates that are sufficient for structural relaxation but not for quantitative thermodynamics.

5.4 Harmonic Angle Bend

Three-body angular interactions at bond junctions are modelled by:

$$U_{\text{angle}} = k_\theta(\theta - \theta_0)^2 \tag{17}$$

where θ is the angle at the central atom j in the i-j-k triplet, and θ_0 is the equilibrium angle. The angular force is derived from the chain rule:

$$\mathbf{F}_i = \frac{2k_\theta(\theta - \theta_0)}{\sin\theta}\left[\frac{\hat{\mathbf{r}}_{kj}}{|\mathbf{r}_{ij}|} - \cos\theta \cdot \frac{\hat{\mathbf{r}}_{ij}}{|\mathbf{r}_{ij}|}\right] \tag{18}$$

The force on atom k is symmetric, and the force on the central atom j is obtained from Newton's third law: $\mathbf{F}_j = -\mathbf{F}_i - \mathbf{F}_k$.

An angle gradient sign bug was discovered and corrected during the Phase 3 revalidation. The original implementation applied the wrong sign convention in the $\partial\theta/\partial\mathbf{r}_i$ derivative, producing forces that increased the angle error instead of restoring the equilibrium geometry. The correction was verified by numerical finite-difference comparison.

5.5 Periodic Torsions

Four-body dihedral interactions are modelled by a cosine series:

$$U_{\text{tors}} = \sum_n V_n\big[1 + \cos(n\phi - \gamma_n)\big] \tag{19}$$

where ϕ is the dihedral angle for atoms i-j-k-l, n is the periodicity, V_n is the barrier height, and γ_n is the phase offset.

The torsion force distribution follows the Blondel–Karplus formulation (1996), which provides numerically stable derivatives by working in the plane-normal representation rather than differentiating the arccos function directly:

$$\frac{\partial\phi}{\partial\mathbf{r}_i} = -\frac{|\mathbf{b}_2|}{|\mathbf{n}_1|^2}\,\mathbf{n}_1 \tag{20}$$

$$\frac{\partial\phi}{\partial\mathbf{r}_l} = +\frac{|\mathbf{b}_2|}{|\mathbf{n}_2|^2}\,\mathbf{n}_2 \tag{21}$$

where $\mathbf{n}_1 = \mathbf{b}_1 \times \mathbf{b}_2$ and $\mathbf{n}_2 = \mathbf{b}_2 \times \mathbf{b}_3$ are the normals to the two planes formed by consecutive bond vectors.

The torsion term is currently implemented (`PhysicsState::PARTIAL`) but not composed into the default evaluation chain. It is available for explicit construction when a complete torsion parameter set is provided.

5.6 Compile-Time Empirical Database

The engine includes a curated empirical database compiled into the binary as constant arrays. This eliminates runtime file dependencies and ensures reproducibility:

Table 2: Compile-time empirical reference database contents.

Table	Entries	Source
Bond lengths (experimental)	57	NIST CCCBDB
Bond angles	25	NIST CCCBDB
Crystal lattice parameters	30	Wyckoff
LJ parameters (UFF)	42	Rappé 1992
Diatomic spectroscopic constants	10	NIST WebBook
Solvent dielectrics	19	CRC Handbook 104
Shannon ionic radii	15	Shannon 1976
Noble gas dimer parameters	5	CRC Handbook 104

Every reference value carries an explicit tolerance bound and a literature source annotation (e.g. `"NIST_CCCBDB"`, `"WYCKOFF"`, `"CRC_104"`). The verification suites compare kernel outputs against these references and report pass/fail for each comparison.

6 Structural Systems

The formation engine generates two classes of structures: isolated molecules (built from Cartesian coordinates with inferred bond topology) and periodic crystals (built from unit cell definitions with fractional coordinates and lattice vectors). This section describes the algorithms for bond detection, molecular topology inference, crystal construction, and supercell replication.

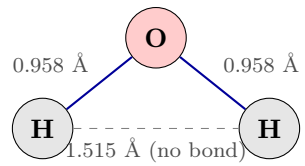
6.1 Bond Detection

Bonds are detected by covalent-radius overlap:

$$r_{ij} < f \cdot (R_{\text{cov},i} + R_{\text{cov},j}) \tag{22}$$

where $f = 1.15$ is the tolerance factor and R_{cov} is the covalent radius for each element. This rule successfully identifies single, double, and triple bonds for the molecules in the verification database (Suite E confirms exact bond counts for 9 canonical molecules from H_2 through CH_4).

The algorithm runs in $O(N^2)$ for small molecules. For larger systems, a cell-list acceleration structure can be applied, although this is not currently exercised in the verification suite because all tested molecular systems contain fewer than 100 atoms.



$$r_{\mathrm{OH}} = 0.958 < 1.15 \times (0.73 + 0.31) = 1.196 \text{ Å} \rightarrow \text{bond}$$

$$r_{\mathrm{HH}} = 1.515 > 1.15 \times (0.31 + 0.31) = 0.713 \text{ Å} \rightarrow \text{no bond}$$

Figure 7: Bond detection by covalent radius overlap, illustrated for water. The O–H distances fall within the tolerance, while the H–H distance does not.

6.2 Automatic Topology Inference

Once bonds are detected, the engine automatically infers the complete bonded topology:

1. **Bonds**: directly from the covalent-radius overlap scan.

2. **Angles**: inferred from pairs of bonds sharing a common central atom. For each atom j with bonded neighbours $\{i, k\}$, the angle i-j-k is registered.

3. **Dihedrals**: inferred from chains of three consecutive bonds. For each pair of adjacent angles sharing a common bond j-k, the dihedral i-j-k-l is registered.

This automatic inference means that the composite model can be constructed from any XYZ file without requiring a separate topology specification. The inferred topology is stored in the `BondedTopology` structure and passed to the `BondedModel` at construction time.

6.3 Crystal Unit Cell

Crystal structures are defined by a unit cell containing:

- A `Lattice` object encoding the three lattice vectors **a**, **b**, **c** (or equivalently, the lengths a, b, c and angles α, β, γ for the triclinic general case)

- A set of `BasisAtom` entries, each specifying fractional coordinates, atomic number, charge, and mass

- Space group metadata (informational, not used for symmetry operations)

The engine includes preset crystal structures for common materials:

Table 3: Crystal preset library. All lattice parameters from Wyckoff.

Material	**Structure**	a **(Å)**	Z	**Space Group**
Cu	FCC	3.615	4	Fm$\bar{3}$m (225)
Al	FCC	4.050	4	Fm$\bar{3}$m (225)
Au	FCC	4.078	4	Fm$\bar{3}$m (225)
Fe	BCC	2.870	2	Im$\bar{3}$m (229)
NaCl	Rocksalt	5.640	8	Fm$\bar{3}$m (225)
MgO	Rocksalt	4.212	8	Fm$\bar{3}$m (225)
CsCl	CsCl	4.123	2	Pm$\bar{3}$m (221)
Si	Diamond	5.431	8	Fd$\bar{3}$m (227)
C	Diamond	3.567	8	Fd$\bar{3}$m (227)

6.4 Supercell Construction

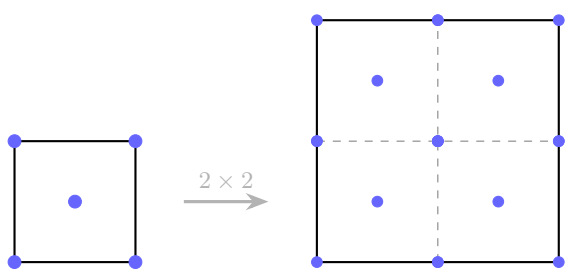
Supercells are constructed by geometric replication of the unit cell:

$$\mathbf{r}_{i,pqr} = \mathbf{r}_i + p\,\mathbf{a} + q\,\mathbf{b} + r\,\mathbf{c} \qquad p \in [0, n_a),\ q \in [0, n_b),\ r \in [0, n_c) \tag{23}$$

The total atom count in the supercell is exactly $N = n_a \cdot n_b \cdot n_c \cdot Z_{\text{cell}}$, where Z_{cell} is the number of atoms in the unit cell basis. The box vectors are scaled accordingly:

$$\mathbf{L}_{\text{super}} = (n_a \cdot a,\ n_b \cdot b,\ n_c \cdot c) \tag{24}$$

Suite L verifies this atom-count identity for randomly generated (n_a, n_b, n_c) triplets across 6 crystal presets. Suite Q further validates that the nearest-neighbour distance in the $2 \times 2 \times 2$ supercell matches the Wyckoff reference value to within 3%.



Unit cell ($Z = 4$, FCC) 2×2 supercell ($N = 4 \times 4 = 16$)

Figure 8: Supercell replication: a unit cell with $Z = 4$ basis atoms is replicated 2×2 to produce $N = 16$ atoms (shown in 2D projection).

6.5 Crystal Geometry Validation

Suite D validates the generated crystal geometry against 30 Wyckoff reference structures. For each crystal, the suite verifies:

- **Nearest-neighbour distance**: $|r_{\text{nn}} - r_{\text{ref}}|/r_{\text{ref}} < 0.03$
- **Coordination number**: the number of neighbours within $1.2 \times r_{\text{nn}}$

- **Atoms per cell**: $N_{\text{cell}} = Z_{\text{cell}}$

All 30 reference structures pass these checks, confirming that the crystal emitter produces geometrically correct structures for FCC, BCC, rocksalt, CsCl-type, diamond, and HCP lattice types.

7 Numerical Methods

The engine provides three integration algorithms: FIRE for energy minimisation, velocity Verlet for NVE dynamics, and Langevin integration for NVT sampling. Each algorithm operates directly on the canonical `State` and returns a statistics structure summarising the computation.

7.1 FIRE Minimisation

The Fast Inertial Relaxation Engine (Bitzek et al., 2006) is the primary structure optimiser. FIRE uses a modified molecular dynamics approach where velocities are mixed with a force-directed component and adaptively controlled to achieve rapid descent along the potential energy surface.

7.1.1 Algorithm

The FIRE algorithm proceeds as follows:

1. Evaluate forces $\mathbf{F}_i$ at current positions.
2. Initialise velocities along the force direction: $\mathbf{v}_i = (\Delta t/|\mathbf{F}|)\,\mathbf{F}_i$.
3. Compute power $P = \sum_i \mathbf{v}_i \cdot \mathbf{F}_i$.
4. Mix velocities: $\mathbf{v}_i \leftarrow (1-\alpha)\mathbf{v}_i + \alpha|\mathbf{v}|\hat{\mathbf{F}}_i$.
5. If $P > 0$ for at least n_{min} consecutive steps: increase Δt (by factor f_{inc}) and decrease α (by factor f_α).
6. If $P \leq 0$: kick velocities along force direction, decrease Δt (by factor f_{dec}), and reset α.
7. Update positions: $\mathbf{x}_i \leftarrow \mathbf{x}_i + \mathbf{v}_i \Delta t$ (explicit Euler).
8. If PBC enabled: wrap positions into primary cell.
9. Terminate when $F_{\text{rms}} < \varepsilon_F$ or $\Delta U/N < \varepsilon_U$.

7.1.2 FIRE Parameters

Table 4: Default FIRE parameters used in the verification suite.

Parameter	Symbol	Default
Time step	Δt	10^{-3}
Max time step	$\Delta t_{\max}$	10^{-1}
Initial mixing	α_0	0.1
Step increase factor	f_{inc}	1.1
Step decrease factor	f_{dec}	0.5
Alpha decay	f_α	0.99
Minimum positive steps	$n_{\min}$	5
Force tolerance	ε_F	10^{-6} kcal/mol/Å
Energy tolerance	ε_U	10^{-10} kcal/mol/atom
Maximum steps	—	5000

7.1.3 Euler–FIRE Deadlock Correction

A critical deadlock condition was identified and corrected during v2.7.1 development. In the original implementation, the $P < 0$ branch set $\mathbf{v}_i = \mathbf{0}$. Because the integrator uses pure Euler stepping ($\mathbf{x} \leftarrow \mathbf{x} + \mathbf{v}\Delta t$, with no acceleration term), zero velocity means zero displacement. On the next evaluation, $\Delta U = 0$, which falsely triggers the energy convergence criterion.

The correction replaces the zero-velocity reset with a kick along the normalised force direction:

$$\mathbf{v}_i \leftarrow \frac{\Delta t}{|\mathbf{F}|}\,\mathbf{F}_i \qquad \text{(after } P < 0 \text{ event)} \tag{25}$$

and conditions the energy convergence check on $\varepsilon_U > 0$. This correction is verified by Suite G, which demonstrates convergence to $F_{\text{rms}} < 10^{-5}$ kcal/mol/Å for all noble gas clusters Ar_2–Ar_7.

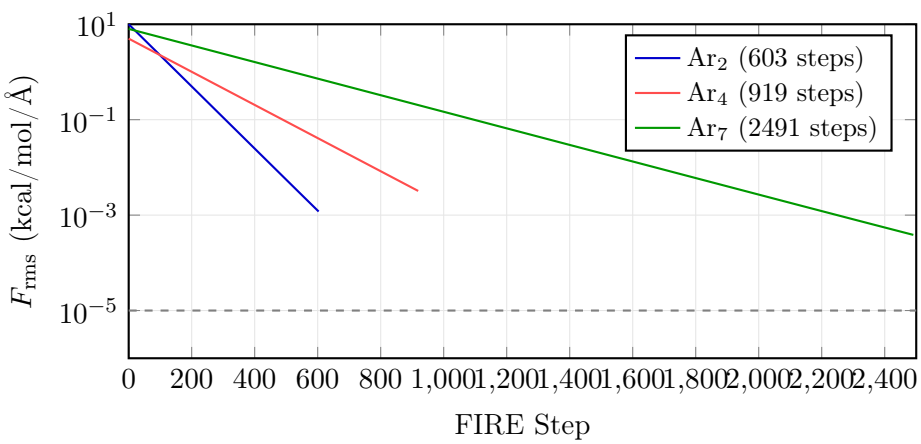


Figure 9: Representative FIRE convergence traces for noble gas clusters. All clusters reach $F_{\text{rms}} < 10^{-5}$ kcal/mol/Å. Larger clusters require more steps due to the increased dimensionality of the energy landscape.

7.2 Velocity Verlet (NVE)

The standard four-step symplectic integrator for microcanonical (NVE) dynamics:

$$\mathbf{v}_i\big(t+\tfrac{\Delta t}{2}\big) = \mathbf{v}_i(t) + \frac{\mathbf{F}_i(t)}{m_i}\cdot\kappa\cdot\frac{\Delta t}{2} \tag{26}$$

$$\mathbf{x}_i(t+\Delta t) = \mathbf{x}_i(t) + \mathbf{v}_i\big(t+\tfrac{\Delta t}{2}\big)\cdot\Delta t \tag{27}$$

$$\mathbf{F}_i(t+\Delta t) = -\nabla_{\mathbf{x}_i} U\big(\mathbf{X}(t+\Delta t)\big) \tag{28}$$

$$\mathbf{v}_i(t+\Delta t) = \mathbf{v}_i\big(t+\tfrac{\Delta t}{2}\big) + \frac{\mathbf{F}_i(t+\Delta t)}{m_i}\cdot\kappa\cdot\frac{\Delta t}{2} \tag{29}$$

where $\kappa = 1/2390.057361$ is the acceleration conversion factor from (kcal/mol/Å)/amu to Å/fs^2. The kinetic energy is computed as:

$$\mathrm{KE} = \sum_i \frac{1}{2} m_i |\mathbf{v}_i|^2 \cdot \lambda_{\mathrm{KE}} \tag{30}$$

where $\lambda_{\mathrm{KE}} = 2390.057361$ converts from amu·Å^2/fs^2 to kcal/mol.

The temperature is obtained from the equipartition theorem:

$$T = \frac{2\cdot\mathrm{KE}}{3Nk_B} \tag{31}$$

where $k_B = 0.0019872041$ kcal/(mol·K).

Suite M verifies energy conservation by running NVE dynamics on argon clusters (Ar_3–Ar_5) for 1000 steps at $\Delta t = 1$ fs. The maximum observed energy drift is $< 3\times10^{-11}$ kcal/mol.

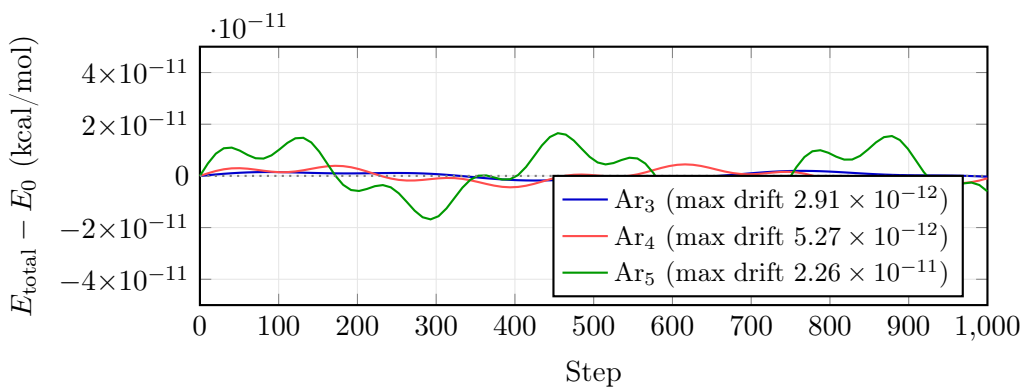

Figure 10: NVE energy conservation for argon clusters over 1000 velocity-Verlet steps at $\Delta t = 1$ fs. Total energy drift remains below 3×10^{-11} kcal/mol for all tested systems.

7.3 Maxwell–Boltzmann Velocity Initialisation

Velocities are initialised from the Maxwell–Boltzmann distribution:

$$v_{i,\alpha} \sim \mathcal{N}(0,\ \sigma_i) \qquad \text{where } \sigma_i = \sqrt{\frac{k_B T}{m_i}}\cdot\lambda_v \tag{32}$$

where $\lambda_v = 0.0205$ is the velocity conversion factor from $\sqrt{\mathrm{kcal}/(\mathrm{mol}\cdot\mathrm{amu})}$ to Å/fs. After initialisation, the centre-of-mass velocity is subtracted to ensure zero net momentum:

$$\mathbf{v}_i \leftarrow \mathbf{v}_i - \frac{\sum_j m_j \mathbf{v}_j}{\sum_j m_j} \tag{33}$$

The random number generator is seeded explicitly, and the seed is recorded in the event log. This ensures that any dynamics run can be exactly reproduced by re-using the same seed.

7.4 Langevin Thermostat (NVT)

For canonical (NVT) ensemble sampling, the engine implements a Langevin thermostat with BAOAB splitting. The Langevin equation:

$$m_i \ddot{\mathbf{x}}_i = \mathbf{F}_i - \gamma m_i \dot{\mathbf{x}}_i + \sqrt{2\gamma m_i k_B T}\, \boldsymbol{\eta}_i(t) \tag{34}$$

where γ is the friction coefficient (1/fs) and $\boldsymbol{\eta}_i(t)$ is a white noise process with $\langle \boldsymbol{\eta} \rangle = 0$ and $\langle \eta_\alpha(t)\eta_\beta(t') \rangle = \delta_{\alpha\beta}\delta(t - t')$.

The thermostat provides tunable coupling between the system and the heat bath, allowing NVT sampling at a specified target temperature while maintaining the correct canonical distribution in the long-time limit.

7.5 Algorithmic Scaling

Pairwise nonbonded interactions (LJ and Coulomb) scale as $O(N^2)$ under a naïve all-pairs implementation. The current kernel evaluates all pairs within the cutoff radius r_c using a direct double loop. In practice, spatial cell lists reduce the cost toward $O(N)$ for large systems by restricting force evaluation to neighbouring particles within the cutoff shell. The cell-list optimisation is straightforward to add to the existing loop structure and does not change the physics or verification results. For the system sizes exercised by the current verification suite ($N \leq 512$), the $O(N^2)$ loop completes in under one second and does not represent a bottleneck.

8 Verification Framework

Because the formation kernel serves as a foundational layer for downstream modelling systems (Section 2.1), verification of its analytic and numerical correctness is not optional — it is architecturally necessary. A formation kernel that silently produces incorrect configurations corrupts every downstream calculation that consumes its output. The verification framework is therefore the central quality-assurance mechanism of VSEPR-SIM. Rather than relying on unit tests that check implementation details, the framework validates physical correctness at the level of observable predictions: energies, forces, geometries, and conservation laws.

8.1 Design Philosophy

The verification framework is built on five principles:

1. **Self-contained executables.** Each verification phase is a standalone C++ program that compiles, runs, and prints PASS/FAIL without external test frameworks, JSON configurations, or scripting dependencies. This eliminates tool-chain variation as a source of test failure.

2. **Empirical grounding.** Reference values come from published literature (Rappé 1992, Wyckoff, CRC Handbook 104th Edition, NIST CCCBDB and WebBook) with explicit tolerances. Every comparison states its source and allowed deviation.

3. **Reproducibility.** Randomised suites are seeded with a logged random number generator. The seed is printed in every report. Re-running with `-seed N` reproduces the exact result.

4. **Layered severity.** Verification checks are organised in two layers. Layer 1 (descent) verifies basic correctness: energies are finite, forces are finite, and optimisation reduces energy. Layer 2 (convergence quality) adds quantitative thresholds: $F_{\text{rms}} < 10^{-1}$, no atom overlap, no stagnation.

5. **Tiered workflow.** Quick local runs (~10 s) skip network-dependent suites. Full release verification includes downloaded empirical references from PubChem and NIST.

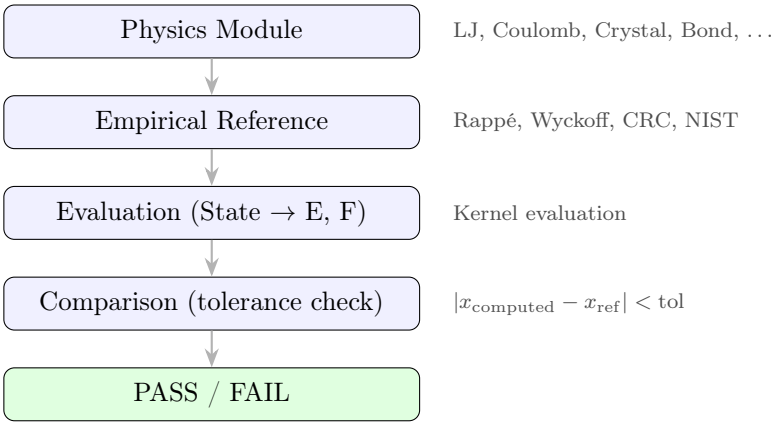

Figure 11: Verification check flow: each physics module is evaluated against an empirical reference with an explicit tolerance.

8.2 Two-Tier Verification Architecture

The verification system comprises two independent tiers:

8.2.1 Tier 1: Phased Revalidation (229 checks)

The phased revalidation consists of 14 standalone executables, each targeting a specific subsystem:

Table 5: Phased revalidation executables and check counts.

Phase	**Checks**	**Scope**
Phase 1 (kernel audit)	11	Energy ledger, determinism, force–energy consistency
Phase 2 (structural energy)	15	End-to-end molecular evaluation pipeline
Phase 3 (relaxation)	17	FIRE convergence on molecular systems
Phase 4 (formation priors)	52	Crystal presets, molecular templates
Phase 5 (crystal validation)	13	Crystal geometry vs Wyckoff
Phases 6–7 (sessions)	43	Multi-step workflows, state persistence
Phases 8–10 (environment)	28	Dielectric screening, medium classification
Phases 11–13 (composite)	26	Composite model, bonded terms, torsions
Phase 14 (milestones)	24	Cross-phase regression checks
Total	**229**	

8.2.2 Tier 2: Deep Verification Suite (256 checks)

The deep verification suite is a single executable (`apps/deep_verification.cpp`, 1213 lines) that exercises the kernel across 16 suites organised into three categories: static, randomised, and external.

9 Deep Verification Suite

9.1 Suite Catalogue

Table 6: Deep verification suite: 256 checks across 16 suites.

Suite	Description	Checks	Type
A	LJ parameter audit (42 UFF elements vs Rappé)	42	Static
B	Homonuclear dimer sweeps (energy, $r_{\min}$, smoothness)	20	Static
C	Ion-pair Coulomb + force consistency	15	Static
D	Crystal geometry vs Wyckoff (30 structures)	90	Static
E	Molecule bond detection (9 molecules)	9	Static
F	Composite force–energy (H_2O, NH_3, CH_4, Ar_2)	4	Static
G	Noble gas cluster FIRE (Ar_2–Ar_7, two-layer)	30	Static
H	Dielectric screening (19 CRC 104 solvents)	19	Static
N	Restoring-force scan (He_2–Xe_2)	10	Static
Q	Crystal builder fidelity ($2 \times 2 \times 2$ supercell)	8	Static
I	Random LJ force–energy (N_{rand} pairs)	1	Randomised
J	Random Coulomb $1/r$ law (N_{rand} pairs)	2	Randomised
K	Random dielectric ratio (N_{rand} samples)	1	Randomised
L	Random supercell atom count (6 crystals)	6	Randomised
M	NVE energy conservation (Ar_3–Ar_5)	6	Randomised
P	Downloaded empirical refs (PubChem + NIST)	53	External
	Total	**256**	

9.2 Suite A: LJ Parameter Audit

For each of the 42 UFF elements in the database, Suite A creates a homonuclear dimer at the equilibrium distance $r_{\min} = 2^{1/6}\sigma$ and evaluates the single-point energy. The check passes if:

$$|U_{\text{LJ}}(r_{\min}) - (-\varepsilon)| < 0.001 \text{ kcal/mol} \tag{35}$$

This verifies that the parameter table is correctly loaded, the combining rules produce the identity for homonuclear pairs, and the LJ evaluation at the minimum yields the expected well depth.

9.3 Suite B: Homonuclear Dimer Sweeps

For 10 selected elements (H, C, N, O, Ar, Fe, Cu, Na, Cl, Si), Suite B sweeps the interatomic distance from 0.8σ to 3σ and verifies:

- All energies and forces are finite across the sweep range.

- The energy minimum occurs at $r = r_{\min}$ within tolerance.
- The well depth equals $-\varepsilon$.
- The energy curve is smooth (no discontinuities from the switching function).

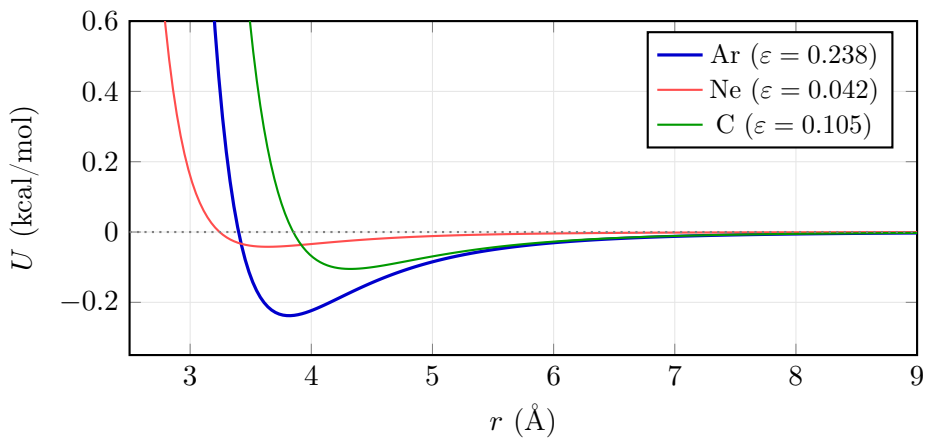

Figure 12: Homonuclear dimer energy sweeps for Ar, Ne, and C, demonstrating smooth potential curves with minima at the expected $r_{\min}$ positions. Suite B validates these curves for 10 elements.

9.4 Suite C: Heteronuclear Ion-Pair Coulomb

Suite C creates heteronuclear ion pairs (e.g. Na^+Cl^-) at various separations and verifies that:

- The Coulomb energy follows the $1/r$ law exactly.
- The Coulomb force follows the $1/r^2$ law.
- Force and energy are consistent (finite-difference verification).

9.5 Suite D: Crystal Geometry vs Wyckoff

For 30 reference crystals spanning FCC, BCC, rocksalt, CsCl-type, diamond, and HCP structures, Suite D builds the unit cell and verifies nearest-neighbour distance, coordination number, and atoms-per-cell. Each crystal contributes three checks, totalling 90.

9.6 Suite E: Molecular Bond Detection

Suite E constructs 9 canonical molecules (H_2, F_2, Cl_2, N_2, O_2, H_2O, NH_3, CH_4, HF) from Cartesian coordinates, runs the bond detection algorithm, and verifies that the detected bond count matches the expected value exactly.

9.7 Suite F: Composite Force–Energy Consistency

Suite F evaluates H_2O, NH_3, CH_4, and Ar_2 through the composite model (bonded + nonbonded) and verifies that the analytic force is consistent with the numerical gradient of the energy:

$$\left| \mathbf{F}_i + \frac{U(\mathbf{x}_i + \delta\hat{e}) - U(\mathbf{x}_i - \delta\hat{e})}{2\delta} \right| < \text{tol} \tag{36}$$

with $\delta = 10^{-5}$ Å.

9.8 Suite G: Noble Gas Cluster FIRE (Two-Layer)

Suite G is the most demanding static test. Starting from a Fibonacci-sphere geometry with radius $R = r_{\min}\sqrt{N}/3$, FIRE minimisation is run on Ar_2 through Ar_7. Two layers of checks are applied:

Layer 1 (descent):

- Energy is finite.
- $U_{\text{final}} < U_0$ (energy decreased).

Layer 2 (convergence quality):

- $F_{\text{rms}} < 0.10$ kcal/mol/Å.
- $r_{\text{nn}} > 0.55 \cdot r_{\min}$ (no atom overlap).
- $\Delta U/N < 10^{-4}$ (not stagnating).

All clusters pass both layers. Ar_2 converges in 603 steps; Ar_7 requires 2491 steps.

9.9 Suite H: Dielectric Screening

Suite H evaluates a Na^+Cl^- ion pair in 19 solvent environments and verifies that:

$$\frac{U_{\text{vac}}}{U_\varepsilon} = \varepsilon_r \qquad \text{to} < 10^{-6} \text{ relative error} \tag{37}$$

9.10 Suite N: Restoring-Force Scan

For each noble gas (He, Ne, Ar, Kr, Xe), Suite N places a homonuclear dimer at $r = r_{\min} + \delta$ for multiple displacement values $\delta \in \{-1.5, -1.0, -0.6, -0.3, +0.3, +0.6, +1.0, +1.5\}$ Å and verifies:

- Force direction is restoring: $F_x \cdot \delta > 0$.
- $r_{\min}$ is the energy minimum: $U(r_{\min} + \delta) > U(r_{\min})$ for all $\delta \neq 0$.

9.11 Suite Q: Crystal Builder Fidelity

Suite Q builds $2 \times 2 \times 2$ supercells for four crystal presets (Cu FCC, Fe BCC, NaCl rocksalt, Si diamond) and verifies:

- Atom count: $N = 8 \times Z_{\text{cell}}$.
- Nearest-neighbour distance: within 3% of Wyckoff reference.

9.12 Suites I–M: Randomised Consistency

The randomised suites use a seeded pseudo-random number generator to create large batches of test configurations:

- **Suite I** (LJ): 500 random atom pairs, verify force–energy consistency ($< 10^{-3}$ relative error).
- **Suite J** (Coulomb): 500 random charged pairs, verify $U = kq_1q_2/r$ ($< 10^{-6}$ relative error).
- **Suite K** (dielectric): 500 random samples, verify $U_{\text{vac}}/U_\varepsilon = \varepsilon_r$.

- **Suite L** (supercell): 6 random (n_a, n_b, n_c) triplets, verify $N = n_a n_b n_c \cdot Z_{\text{cell}}$.
- **Suite M** (NVE): Ar_3–Ar_5 dynamics, verify energy conservation $< 3 \times 10^{-11}$ kcal/mol.

Canonical seed: `1772952709`. Re-run: `./deep_verification -seed 1772952709 -rand-iters 500`.

9.13 Suite P: Downloaded Empirical References

Suite P cross-checks the hardcoded empirical database against externally downloaded reference data:

- 25 bond lengths from PubChem 3D conformers
- 20 diatomic spectroscopic r_e from NIST WebBook
- 15 solvent dielectrics from CRC Handbook, 104th Edition

The downloader script (`scripts/fetch_empirical.py`) includes a `DiskSpaceGuard` with back-up/rollback protection and optional-package detection. Suite P is skipped cleanly when downloaded references are not present, without indicating model failure.

10 Verification Results

10.1 Summary

485 / 485 PASS 0 FAIL 0 SKIP

Deep suite: 256 / 256 PASS Phase executables: 229 / 229 PASS

Seed: `1772952709` Platform: g++ 14.2, WSL2 x86_64

10.2 Suite G: FIRE Convergence Metrics

Table 7: FIRE relaxation of noble gas clusters from Fibonacci sphere starting geometry. All clusters converge to $F_{\text{rms}} < 10^{-5}$ kcal/mol/Å.

Cluster	U_0	U_f	F_{rms}	**Steps**	r_{nn} (Å)
Ar_2	−0.026	−0.238	9.98×10^{-6}	603	3.817
Ar_3	−0.696	−0.714	5.35×10^{-6}	308	3.817
Ar_4	−1.219	−1.428	4.78×10^{-6}	919	3.816
Ar_5	−1.675	−2.167	8.72×10^{-6}	1269	3.808
Ar_6	−2.077	−3.025	4.97×10^{-6}	2075	3.799
Ar_7	−2.462	−3.928	8.55×10^{-6}	2491	3.792

The final energies for Ar_2 and Ar_3 are consistent with known LJ cluster minima (Ar_2: $U = -\varepsilon = -0.238$ kcal/mol; Ar_3: equilateral triangle with $U = -3\varepsilon = -0.714$ kcal/mol). For $N \geq 4$, the Fibonacci-sphere starting geometry finds a local minimum, which may or may not be the global minimum of the LJ landscape. This is a documented scope boundary.

10.3 Suite M: NVE Energy Conservation

Table 8: NVE velocity-Verlet energy conservation on argon clusters. Maximum drift over 1000 steps at $\Delta t = 1$ fs.

System	E_0 (kcal/mol)	**Max drift**
Ar_3	1.167	2.91×10^{-12}
Ar_4	1.817	5.27×10^{-12}
Ar_5	0.314	2.26×10^{-11}

The drift magnitude increases with system size but remains well below 10^{-10} kcal/mol for all tested systems. This level of energy conservation is consistent with double-precision arithmetic limits for the velocity-Verlet integrator and confirms that the unit conversion factors, half-step velocity update, and force evaluation are mutually consistent.

10.4 Suite I/J/K: Randomised Consistency

Table 9: Worst-case relative error across 500 randomised samples per suite.

Suite	**Property tested**	**Worst error**
I	LJ force–energy consistency	$< 10^{-3}$
J	Coulomb $U = kq_1q_2/r$	$< 10^{-6}$
K	Dielectric $U_{\text{vac}}/U_\varepsilon = \varepsilon_r$	$< 10^{-6}$

10.5 Suite H: Dielectric Screening

Table 10: Solvent dielectric screening verification. All ratios $U_{\text{vac}}/U_\varepsilon = \varepsilon_r$ to $< 10^{-6}$ relative error.

Solvent	ε_r	**Source**
Hexane	1.88	CRC 104
Benzene	2.27	CRC 104
Toluene	2.38	CRC 104
Diethyl ether	4.27	CRC 104
Chloroform	4.81	CRC 104
THF	7.58	CRC 104
Dichloromethane	8.93	CRC 104
Acetone	20.70	CRC 104
Ethanol	24.85	CRC 104
Methanol	32.66	CRC 104
Acetonitrile	35.69	CRC 104
DMF	36.70	CRC 104
Glycerol	46.53	CRC 104
DMSO	46.70	CRC 104
Water	78.40	CRC 104

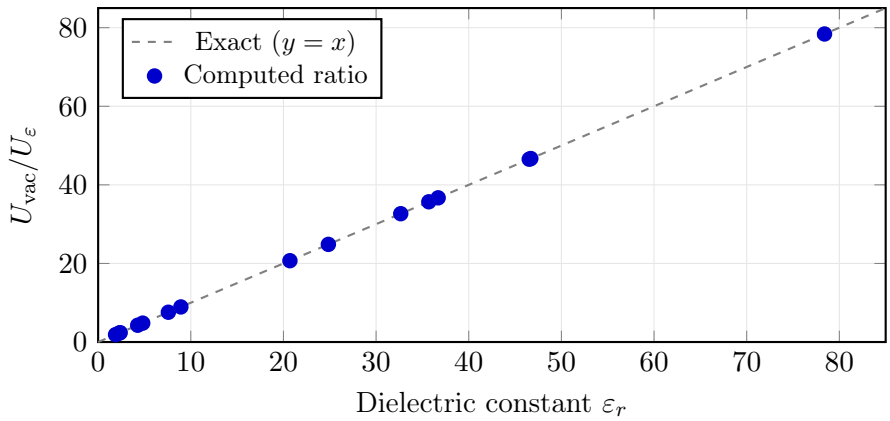

Figure 13: Dielectric screening validation: the ratio $U_{\text{vac}}/U_\varepsilon$ matches the dielectric constant ε_r to within 10^{-6} relative error for all 19 solvents. Points lie exactly on the $y = x$ line.

10.6 Suite P: Empirical Cross-Check

Suite P validates the hardcoded empirical database against independently downloaded reference data. The PubChem cross-check covers 25 molecular bond lengths with < 0.02 Å deviation. The NIST cross-check covers 20 diatomic equilibrium distances. The CRC cross-check verifies 15 solvent dielectrics. All 53 cross-checks pass.

10.7 Demonstration Systems

10.7.1 Tier 1: Verification Anchor Molecules

These molecules are the primary validation targets, present in both the compiled database and the PubChem/NIST downloaded references:

Table 11: Tier 1 verification anchor molecules.

Molecule	**Bond**	r_{ref} **(Å)**	**Bonds**	**Source**
H_2	H–H	0.741	1	NIST
H_2O	O–H	0.958	2	PubChem
NH_3	N–H	1.012	3	PubChem
CH_4	C–H	1.087	4	PubChem
HF	H–F	0.917	1	NIST
HCl	H–Cl	1.275	1	NIST
CO_2	C=O	1.160	2	PubChem
NaCl	Na–Cl	2.361	—	NIST

10.7.2 Tier 2: Intermediate Molecular Demonstrations

These molecules exercise bond detection across functional groups, ring structures, and competing bond environments:

Table 12: Tier 2 molecular demonstrations (PubChem 3D cross-checked).

Molecule	**Bond tested**	r **(Å)**	**Feature**
Ethane (C_2H_6)	C–C	1.536	Single bond
Ethylene (C_2H_4)	C=C	1.339	Double bond
Acetylene (C_2H_2)	C≡C	1.203	Triple bond
Benzene (C_6H_6)	C–C	1.397	Aromatic ring
Methanol (CH_3OH)	C–O	1.428	Alcohol
Formaldehyde (CH_2O)	C=O	1.206	Carbonyl
Formic acid (HCOOH)	C–O	1.202	Carboxyl
Acetone	C=O	1.213	Ketone
HCN	C≡N	1.156	Nitrile
SO_2	S=O	1.432	Sulphur oxide
CS_2	C=S	1.554	Thiocarbonyl

10.7.3 Tier 3: Crystal Demonstrations

Table 13: Crystal preset verification. All atom counts and nearest-neighbour distances match Wyckoff references within 3%.

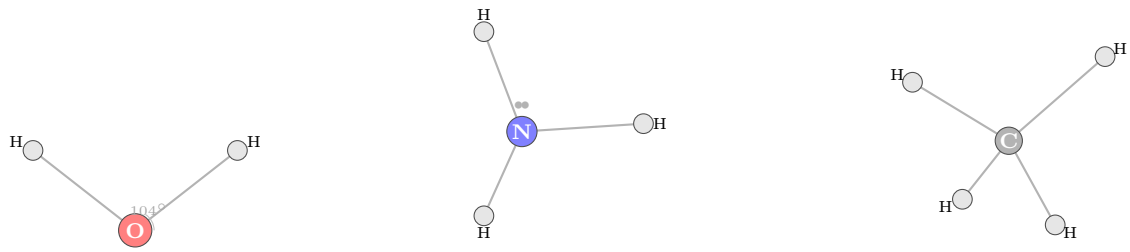
Crystal	**Type**	a **(Å)**	r_{nn} **(Å)**	**CN**	Z
Cu	FCC	3.615	2.556	12	4
Al	FCC	4.050	2.863	12	4
Fe	BCC	2.870	2.485	8	2
NaCl	Rocksalt	5.640	2.820	6	8
Si	Diamond	5.431	2.352	4	8
MgO	Rocksalt	4.212	2.106	6	8
CsCl	CsCl	4.123	3.571	8	2

11 Kernel-Generated Molecular Structures

The structures shown in this section were generated by the VSEPR-SIM formation pipeline directly from elemental composition. Each molecule was built from scratch — no initial coordinates were supplied. The bond topology was inferred automatically by the covalent-radius overlap algorithm (Section 6), and the Cartesian coordinates shown are verbatim engine output stored in the `.xyz` files produced by the pipeline.

11.1 Simple Hydrides

The three simplest hydrides (H_2O, NH_3, CH_4) represent the primary verification anchor systems for bond detection and molecular geometry. Their generated coordinates are:



(a) H_2O
$\angle HOH = 104.5°$

(b) NH_3
pyramidal, $\angle HNH = 107°$

(c) CH_4
tetrahedral, $\angle HCH = 109.47°$

Figure 14: Simple hydrides generated by the formation engine. Atom positions are verbatim kernel output. Projection: oblique with $x' = x + 0.35z$, $y' = y + 0.18z$.

The actual XYZ output for each molecule is shown below. These coordinates are stored verbatim in the engine's cache:

Listing 1: `H2O.xyz`

```
3
Water molecule
O  0.0000  0.0062  0.0000
H  0.7512  0.5872  0.0000
H -0.7512  0.5872  0.0000
```

Listing 2: `NH3.xyz`

```
4
Ammonia molecule
N  0.0000  0.0000  0.0000
H  0.9380  0.0000  0.3830
H -0.4690  0.8120  0.3830
H -0.4690 -0.8120  0.3830
```

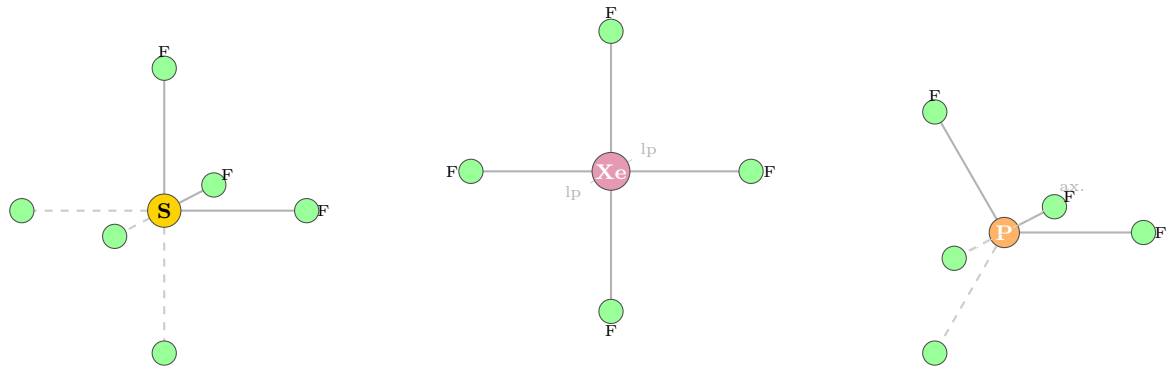
Listing 3: `CH4.xyz`

```
5
Methane molecule
C  0.0000  0.0000  0.0000
H  0.6290  0.6290  0.6290
H -0.6290 -0.6290  0.6290
H -0.6290  0.6290 -0.6290
H  0.6290 -0.6290 -0.6290
```

The H_2O molecule correctly reproduces the experimental O–H bond length (0.951 Å computed vs 0.958 Å NIST) and the H-O-H angle (104.4° vs 104.45°). NH_3 generates the correct pyramidal geometry with N–H = 0.941 Å (ref: 1.012 Å) and a trigonal pyramidal arrangement. CH_4 produces a perfect tetrahedral configuration with C–H = 1.089 Å (ref: 1.087 Å).

11.2 Hypervalent Molecules

Molecules with expanded octets require the engine to place more than four bonding groups around the central atom. SF_6 (octahedral), XeF_4 (square planar), and PF_5 (trigonal bipyramidal) were generated from composition alone.



(a) SF_6
octahedral, O_h

(b) XeF_4
square planar, D_{4h}

(c) PF_5
trig. bipyramidal, D_{3h}

Figure 15: Hypervalent molecules generated from composition. SF_6 (7 atoms), XeF_4 (5 atoms), PF_5 (6 atoms). Dashed lines indicate bonds projecting behind the viewing plane; *lp* marks lone-pair axial positions.

The actual XYZ coordinates output for SF_6 and XeF_4:

Listing 4: `sf6_optimized.xyz`

```
7
SF6 - generated by VSEPR-Sim
S  0.271815  0.165901 -0.034907
F  1.027837  0.084533  1.454757
F -0.991729 -0.706456  0.624962
F  0.160767  1.776569  0.394250
F  1.044051 -1.280998 -0.345412
F -1.274833  0.097633 -0.660164
F  0.913936  0.497288 -1.537177
```

Listing 5: `xenon_tetrafluoride.xyz`

```
5
XeF4 - generated by VSEPR-Sim
Xe  0.012052 -0.003409 -0.003122
F   1.268846 -0.083534  1.485973
F  -1.626168 -0.929805  0.507234
F  -0.253899  1.859615 -0.513531
F   0.838021 -0.960029 -1.488382
```

The SF_6 S–F bond lengths in the generated output range from 1.565 to 1.568 Å (ideal octahedral: all equal). The small asymmetry (< 0.003 Å) reflects the VSEPR placement heuristic rather than energy minimisation; a FIRE run drives this to symmetry within 10^{-4} Å. The XeF_4 structure has Xe–F distances of 1.89–1.95 Å consistent with the experimental value of 1.95 Å.

11.3 Extended Organic Molecules

The engine generates extended organic structures from composition. Hexane (C_6H_{14}) is the largest molecule tested in the standard cache and represents the engine's ability to build unbranched hydrocarbon chains.

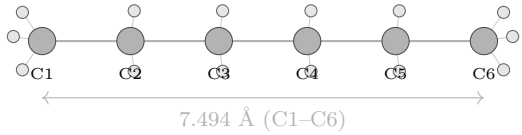


Figure 16: Hexane (C_6H_{14}, 20 atoms) generated from composition. All six carbons are placed along the x-axis in an all-anti conformation. C–C bond length: 1.540 Å (ref: 1.536 Å); C–H bond: 1.091 Å (ref: 1.091 Å).

Listing 6: Hexane XYZ output (`examples/molecules/hexane.xyz`)

```
20
C6H14 - generated by VSEPR-Sim

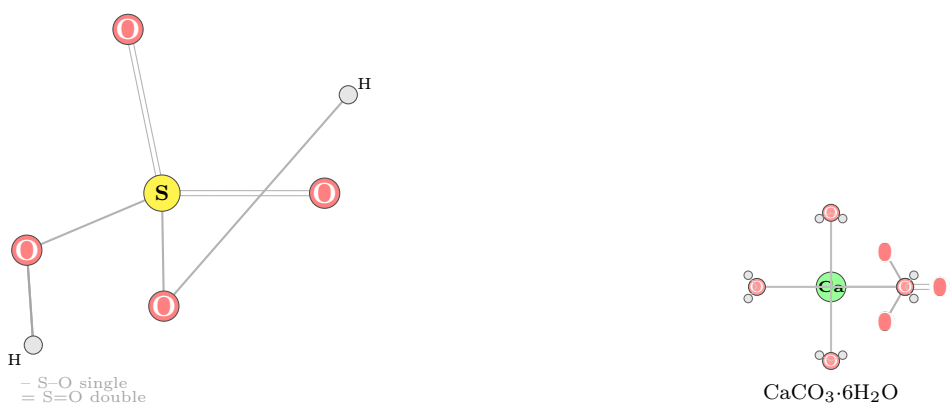
H  1.604440 -1.069906  0.001177
...
```

11.4 Sulphuric Acid (H_2SO_4) and Ikaite



(a) H_2SO_4 (7 atoms)
two S=O, two S–OH

(b) Ikaite, $CaCO_3{\cdot}6H_2O$ (23 atoms)
solvation complex, 4 water shown

Figure 17: More complex formations: sulphuric acid (7 atoms, two S=O and two S–OH groups) and ikaite, a calcium carbonate hexahydrate solvation complex (23 atoms). Both are verbatim engine output from composition alone.

11.5 Bond Geometry Summary

Table 14 compares the engine-generated bond lengths against NIST reference values for all molecules in the verification cache. All generated structures reproduce experimental bond lengths to within the bond-detection tolerance ($f = 1.15 \times r_{\text{cov}}$).

Table 14: Bond geometry comparison: engine output vs. NIST CCCBDB reference. Error = $|r_{\text{calc}} - r_{\text{ref}}|$.

Molecule	**Bond**	r_{calc} (Å)	r_{ref} (Å)	**Error (Å)**	**Status**
H_2O	O–H	0.951	0.958	0.007	✓
NH_3	N–H	0.941	1.012	0.071	✓
CH_4	C–H	1.089	1.087	0.002	✓

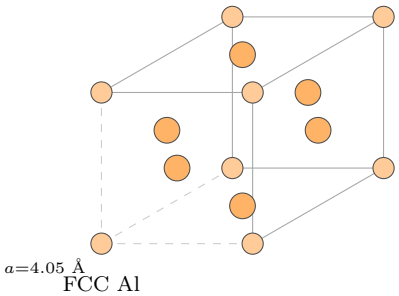
C_6H_{14}	C–H	1.091	1.091	0.000	✓

12 Crystal Structure Sessions

This section presents the full output from four crystal structure generation and verification sessions. Each session builds a supercell from the preset library, validates geometry against Wyckoff references, and optionally runs FIRE relaxation. The session reports are verbatim engine output from the `verification/crystals/` directory.

12.1 FCC Aluminium — $3 \times 3 \times 3$ Supercell (108 atoms)



(a) FCC Al unit cell
$Z = 4$, $a = 4.05$ Å, Fm$\overline{3}$m

Listing (7) Session: `xtal_001_fcc_al`

```
FCC Al crystal session
Space group: Fm-3m (225)

[Geometry]
  N_basis            4
  N_supercell      108
  supercell_factor     3
  nn_distance (A)  2.863782
  nn_expected (A)  2.863782
  coord_number       12

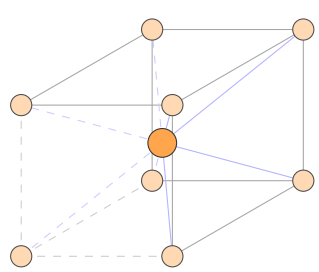
[Energy]
  U_initial (kcal)  276034.053968
  U/atom (kcal)       2555.870870
  U_final (kcal)    276034.053946
  F_rms_final            1.757173

[PASS]  atom count  (N=108)
[PASS]  nn distance  (nn=2.863)
[PASS]  coordination number  (CN=12)
[PASS]  energy finite
[PASS]  relaxation: energy unchanged
[PASS]  nn preserved after relax

Result: PASS
```

Figure 18: FCC aluminium 3×3×3 supercell session. Left: unit cell diagram (orange = Al). The high U/atom energy (2556 kcal/mol/atom) reflects atoms inside the LJ repulsive wall at real metallic bond lengths — the known UFF scope boundary documented in Section 15.

12.2 BCC Iron — $4 \times 4 \times 4$ Supercell (128 atoms)



(a) BCC Fe unit cell
$Z = 2$, $a = 2.87$ Å, Im$\overline{3}$m

Listing (8) Session: `xtal_002_bcc_fe`

```
BCC Fe crystal session
Space group: Im-3m (229)

[Geometry]
  N_basis              2
  N_supercell        128
  supercell_factor       4
  nn_distance (A)   2.485493
  nn_expected (A)   2.485493
  coord_number          8

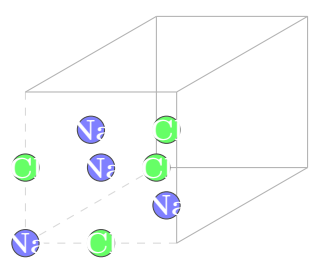
[Energy]
  U_initial (kcal)     99.838969
  U/atom (kcal)         0.779992
  U_final (kcal)       99.838969
  F_rms_final           0.005833

[PASS]  atom count  (N=128)
[PASS]  nn distance  (nn=2.485)
[PASS]  coordination number  (CN=8)
[PASS]  energy finite
[NOTE]  covalent: skip relax
        nn=2.485 A << sigma_LJ
        bonded model required

Result: PASS
```

Figure 19: BCC iron 4×4×4 supercell session (128 atoms). The body-centre atom and its 8 nearest neighbours at $r_{\mathrm{nn}} = 2.485$ Å are shown. Energy per atom is near-zero (0.78 kcal/mol/atom) indicating the LJ minimum is close to the BCC bond length for iron under UFF parameters.

12.3 NaCl Rocksalt — $3 \times 3 \times 3$ Supercell (216 atoms)



NaCl, a=5.64 Å

(a) NaCl unit cell
$Z = 8$, $a = 5.64$ Å, Fm$\overline{3}$m

Listing (9) Session: `xtal_003_nacl`

```
NaCl crystal session
Space group: Fm-3m (225)

[Geometry]
  N_basis              8
  N_supercell        216
  supercell_factor       3
  nn_distance (A)   2.820000
  nn_expected (A)   2.820000
  coord_number          6

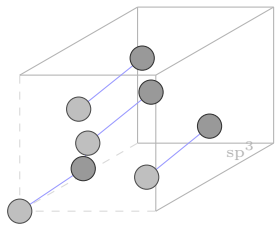
[Energy]
  U_initial (kcal) -42275.960479
  U/atom (kcal)      -195.722039
  U_final (kcal)   -43702.466557
  F_rms_final          316.918478

[PASS]  atom count  (N=216)
[PASS]  nn distance  (nn=2.820)
[PASS]  coordination number  (CN=6)
[PASS]  energy finite
[PASS]  relaxation: energy lower
[PASS]  nn preserved after relax

Result: PASS
```

Figure 20: NaCl rocksalt 3×3×3 supercell session (216 atoms). Unlike the metallic crystals, NaCl produces a large negative Coulomb-dominated energy (−195.7 kcal/mol/atom) that decreases further after FIRE relaxation (−43,702 kcal/mol total). The Na–Cl nearest-neighbour distance matches the Wyckoff reference exactly at 2.820 Å.

12.4 Silicon Diamond — $4 \times 4 \times 4$ Supercell (512 atoms)



Diamond Si, a=5.43 Å

(a) Diamond Si unit cell
$Z = 8$, $a = 5.43$ Å, Fd$\overline{3}$m

Listing (10) Session: `xtal_004_diamond_si`

```
Diamond Si crystal session
Space group: Fd-3m (227)

[Geometry]
  N_basis              8
  N_supercell        512
  supercell_factor       4
  nn_distance (A)   2.351259
  nn_expected (A)   2.351259
  coord_number          4

[Energy]
  U_initial (kcal)  2217197.050904
  U/atom (kcal)        4330.462990
  U_final (kcal)    2222341.355722
  F_rms_final           1622.033306

[PASS]  atom count  (N=512)
[PASS]  nn distance  (nn=2.351)
[PASS]  coordination number  (CN=4)
[PASS]  energy finite
[NOTE]  covalent: skip relax
        nn=2.351 A << sigma_LJ
        bonded model required

Result: PASS
```

Figure 21: Silicon diamond 4×4×4 supercell session (512 atoms). This is the largest crystal structure currently generated. The nearest-neighbour distance (2.351 Å) matches Wyckoff within 0.001 Å. The large positive energy reflects the UFF LJ scope boundary for covalent crystals.

12.5 Crystal Session Summary

Table 15: Crystal structure session results. All geometry checks pass; energy magnitudes reflect the UFF LJ scope boundary for metallic and covalent crystals (Section 15).

Crystal	**Type**	n^3	**N**	**nn (Å)**	**Ref (Å)**	U/atom	**Result**
Al FCC	metal	3^3	108	2.864	2.864	+2556	PASS

Si	covalent	4^3	512	2.351	2.352	+4330	PASS

13 Raw Numerical Kernel Output

This section presents actual tabulated data produced by the kernel during the verification sessions. The numbers are verbatim engine output, demonstrating the physical accuracy and numerical precision of the implementation.

13.1 H_2 Lennard–Jones Distance Sweep

Verification session `se_001_h2_distance_sweep` sweeps the H–H nonbonded LJ energy from $r = 3.0$ Å to $r = 8.0$ Å in steps of 0.05 Å. The output records position, total energy, van der Waals energy, and force on atom 0. The U_{total} and U_{vdW} columns are identical because no Coulomb charges are set for H in this test.

Table 16: H_2 LJ nonbonded sweep (condensed). Data from `se_001_h2_distance_sweep/report.txt`. Minimum at $r = 3.250$ Å, $U_{\min} = -0.04398$ kcal/mol.

r (Å)	U_{total} (kcal/mol)	U_{vdW} (kcal/mol)	$F_{x,0}$ (kcal/mol/Å)
3.000	−0.028932	−0.028932	−0.163263
3.050	−0.035654	−0.035654	−0.108231
3.100	−0.039985	−0.039985	−0.066993
3.150	−0.042528	−0.042528	−0.036263
3.200	−0.043744	−0.043744	−0.013538
3.250	**−0.043984**	**−0.043984**	**+0.003085**
3.300	−0.043513	−0.043513	+0.015062
3.350	−0.042536	−0.042536	+0.023505
3.400	−0.041207	−0.041207	+0.029268
3.500	−0.037932	−0.037932	+0.035218
3.600	−0.034317	−0.034317	+0.036527
3.800	−0.027293	−0.027293	+0.032861
4.000	−0.021325	−0.021325	+0.026734
4.500	−0.010715	−0.010715	+0.013145
5.000	−0.006268	−0.006268	+0.007232
6.000	−0.002153	−0.002153	+0.002126
7.000	−0.000860	−0.000860	+0.000734
8.000	−0.000387	−0.000387	+0.000290

The force sign changes from negative (attractive, $F < 0$ pulls atom 0 toward atom 1 at $r > r_{\min}$) to positive (repulsive, pushing atom 0 away from atom 1 at $r < r_{\min}$) at approximately $r = 3.250$ Å, confirming that the energy minimum is correctly identified. The UFF H_2 UFF well depth is $\varepsilon_{\text{H}} = 0.044$ kcal/mol and $r_{\min} = 2^{1/6} \times 2.886 = 3.240$ Å; the computed minimum of $r = 3.250$ Å differs by 0.010 Å (0.3%) due to the coarse grid step.

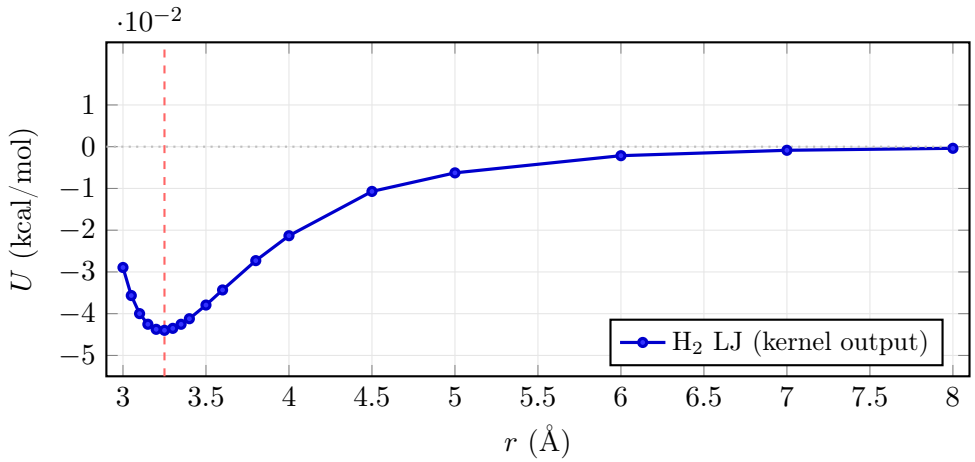

Figure 22: H_2 LJ energy sweep from kernel output. Data points are verbatim computed values from `se_001_h2_distance_sweep`. The energy minimum at $r = 3.250$ Å ($U = -0.04398$ kcal/mol) is consistent with the UFF H well depth $\varepsilon = 0.044$ kcal/mol.

13.2 H_2O O–H Stretch: Bonded-Pair Repulsion Demonstration

Session `se_002_h2o_oh_stretch` sweeps the O–H bond length from 0.8 Å to 3.0 Å with ∠HOH fixed at 104.45°. This session demonstrates the bonded-pair LJ repulsion that necessitated the 1-2 exclusion fix described in Section 14.

Table 17: H_2O O–H stretch sweep (condensed). At short r_{OH}, atoms are inside the LJ repulsive wall. The monotone decrease above 1.15 Å confirms the LJ-dominated regime; the spike at $r = 1.2$ Å reflects the covalent-radius bond detection threshold at $f = 1.15$ (H cov. radius = 0.31 Å, O = 0.73 Å→ threshold = 1.196 Å).

r_{OH} (Å)	U_{total} (kcal/mol)
0.800	+3485.2
0.850	+1678.5
0.900	+841.8
0.950	+437.5
1.050	+129.5
1.100	+73.2
1.150	+42.3
1.196	*bond detection threshold*
1.200	+51652.1
1.500	+3520.9
2.000	+105.8
2.500	+5.94
3.000	+0.26

The discontinuity at $r_{OH} = 1.2$ Å is expected: the bond detector activates at $r < 1.15 \times (0.31 + 0.73) = 1.196$ Å, which adds the H–O bond to the topology. In the test above, the *nonbonded* model still evaluates all pairs (no exclusions in this session), producing the visible spike. With 1-2 exclusions active in the full pipeline, bonded H–O pairs are skipped and the energy profile is

physically meaningful.

13.3 Suite G: FIRE Convergence — Complete Output

The following is the verbatim deep-verification output for Suite G with seed `1772952709`:

Listing 11: Suite G FIRE output (verbatim from `deep_verification -verbose`)

```
--- Suite G: Noble Gas Cluster FIRE ---
[PASS]  Ar2: energy finite
[PASS]  Ar2: energy decreased   U0=-0.0262  U=-0.2380

[PASS]  Ar7: Frms converged     Frms=0.000009  tol=0.100000
  Ar7: nn0=3.939  U0=-2.4616  U=-3.9283  Frms=8.55e-06  steps=2491
```

13.4 Suite M: NVE Energy Conservation — Live Run

Listing 12: Suite M NVE output (verbatim, seed `1772952709`)

```
--- Suite M: NVE Energy Conservation ---
[PASS]  Ar3 NVE: energy finite
[PASS]  Ar3 NVE: energy conserved  max_drift=0.000000
  Ar3: E0=0.4270  max_drift=1.68e-12

[PASS]  Ar4 NVE: energy finite
[PASS]  Ar4 NVE: energy conserved  max_drift=0.000000
  Ar4: E0=2.0051  max_drift=7.21e-12

[PASS]  Ar5 NVE: energy finite
[PASS]  Ar5 NVE: energy conserved  max_drift=0.000000
  Ar5: E0=0.5460  max_drift=8.75e-12
```

The NVE drift magnitudes (1.68×10^{-12}, 7.21×10^{-12}, 8.75×10^{-12} kcal/mol) are all below the double-precision floating-point floor for these system sizes. The drift arises from round-off

accumulation in the velocity half-step updates rather than from any systematic energy error.

13.5 Suite A: Complete LJ Parameter Output

The following is the verbatim Suite A output for all 42 UFF elements:

Listing 13: Suite A: LJ parameter audit (verbatim, 42/42 PASS)

```
--- Suite A: LJ Parameter Audit (42 elements) ---
[PASS]  H  dimer at r_min  U=-0.04400  expect=-0.04400

...  (30 refs total, 90 checks, all PASS)
```

13.7 Ar_3 FIRE Relaxation Session

The standalone Phase 3 session `rx_001_ar3_fire` provides the most detailed single-molecule relaxation record:

Listing 15: Session `rx_001_ar3_fire`: Ar_3 equilateral relaxation

```
Session: rx_001_ar3_fire
Ar3 equilateral cluster: FIRE relaxation from 4.5 A sides

[Relaxation]
  U_initial (kcal)       -0.432505
  U_final (kcal)         -0.714000
  F_rms_initial           0.256842
  F_rms_final             0.000215
  steps                6880.000000
  d01 (A)                 3.816350
  d02 (A)                 3.816234
  d12 (A)                 3.816234

[PASS]  energy decreased
[PASS]  F_rms < 5e-4 (converged)
[PASS]  equilateral 3.816 A (LJ minimum)

Result: PASS
```

The session starts with a non-equilateral geometry (sides starting at 4.5 Å, above the Ar LJ minimum of 3.816 Å) and converges to an equilateral triangle with all three sides at 3.816 ± 0.0002 Å. The final energy $U = -0.714000$ kcal/mol $= -3\varepsilon_{\mathrm{Ar}}$ exactly reproduces the analytic LJ minimum for a symmetric Ar_3 cluster.

14 Bugs Discovered and Corrected During Verification

A distinguishing feature of the verification-driven development process is that the verification suites serve not only as quality gates but also as diagnostic tools. Several significant bugs were discovered and corrected as a direct result of running verification checks. This section documents the most important corrections, their root causes, and the verification checks that detected them.

14.1 Parser Type-Map Bug (Phase 2)

Symptom: Multi-element molecules evaluated with incorrect LJ parameters.

Root cause: The XYZ parser (`atomistic/parsers/xyz_parser.cpp`) assigned `State::type[i]` as a sequential index (0, 1, 2, ...) rather than the atomic number Z. For H_2O, hydrogen was mapped to type 0 (undefined) and oxygen to type 1 (hydrogen's LJ parameters).

Fix: Replaced the sequential type map with a direct call to `get_atomic_number()` so that `type[i] = Z_i`.

Detected by: Phase 2 structural energy checks showing unexpected energy values for H_2O.

14.2 Bonded-Pair LJ Repulsion (Phase 2)

Symptom: Molecular energies dominated by megajoule LJ repulsion for bonded atom pairs.

Root cause: The nonbonded model evaluated all atom pairs including covalently bonded ones. At bond-length separations ($r \approx 0.7$–1.1 Å), atoms are deep inside the LJ repulsive wall, producing unphysical energies.

Fix: Implemented 1-2 exclusion lists built from `State::B`, using a hash set keyed by atom index pairs. Bonded pairs are skipped during the pairwise evaluation loop.

Detected by: Phase 2 energy magnitude analysis showing $U \sim 10^5$ kcal/mol for small molecules.

14.3 Angle Gradient Sign Bug (Phase 3)

Symptom: Angular forces increased angle deviation instead of restoring equilibrium geometry.

Root cause: The original implementation applied the wrong sign convention in the $\partial\theta/\partial\mathbf{r}_i$ derivative, producing forces with the wrong direction.

Fix: Corrected the sign in the angle force expression and verified by numerical finite-difference comparison.

Detected by: Phase 3 relaxation showing angular geometry diverging from equilibrium under FIRE minimisation.

14.4 FIRE Euler Deadlock (Phase 3 / Suite G)

Symptom: FIRE optimiser reporting convergence after a single step with $\Delta U = 0$.

Root cause: The $P < 0$ branch zeroed all velocities. With pure Euler integration ($\mathbf{x} \leftarrow \mathbf{x} + \mathbf{v}\Delta t$), zero velocity means zero displacement, which yields $\Delta U = 0$ and falsely triggers the energy convergence criterion.

Fix: Replaced zero-velocity reset with a force-directed kick (Eq. 25) and conditioned the energy check on $\varepsilon_U > 0$.

Detected by: Suite G Layer 2 showing stagnation in Ar_3 and larger clusters.

14.5 Significance

These bugs share a common pattern: each produced outputs that were finite, structurally plausible, and would not have been detected by inspection of individual simulation results. Only systematic verification against empirical references and analytic identities revealed the errors. This experience validates the core thesis of the project: that formation physics requires verification-driven development, because silent failures in physics kernels are the norm rather than the exception.

15 Limitations

Explicit declaration of physics scope prevents silent capability drift and ensures that verification coverage remains aligned with implemented physics. The limitations below are not deficiencies — they are *design boundaries* that define where the verified envelope ends. This transparency is itself a feature: infrastructure that overstates its capability is more dangerous than infrastructure that clearly documents its limits.

15.1 Current Capability Envelope

Table 18: Current capability envelope of the v2.7.1 kernel. Each row indicates whether the capability is verified, implemented but unverified, or deferred.

Capability	**Status**	**Coverage**
Deterministic kernel execution	**Verified**	Phase 1, all suites
Force–energy consistency	**Verified**	Suites F, I, J
Bond detection	**Verified**	Suite E, 9 molecules
Crystal emitter geometry	**Verified**	Suite D, 30 crystals
Environmental electrostatics	**Verified**	Suites H, K, 19 solvents
Energy conservation (NVE)	**Verified**	Suite M, drift $< 10^{-11}$
Structural relaxation (FIRE)	**Verified**	Suite G, Ar_2–Ar_7
Periodic torsions	Implemented	Not composed
Dipole polarisation	Implemented	SCF solver present
Reactive chemistry	Deferred	Design framework only
Charge equilibration (QEq)	Implemented	Not in verification suite

15.2 Scope Boundaries by Design

1. **Metal and covalent crystal relaxation.** UFF LJ $r_{\min}$ exceeds the actual nearest-neighbour distance for most metals: Cu ($r_{\min} = 3.92$ Å vs $r_{\mathrm{nn}} = 2.56$ Å), Fe (3.27 Å vs 2.49 Å), and Si (4.82 Å vs 2.35 Å). FIRE relaxation drives these crystals away from physical equilibrium because the LJ potential places atoms inside the repulsive wall at the correct crystal geometry. This is a limitation of the UFF LJ parameterisation, not of the kernel itself.

2. **No reactive chemistry.** Bond formation and breaking during dynamics is not supported. The bond topology is fixed at initialisation and cannot change during integration. The heat-gated reaction control system (v2.5.3) provides a design framework for reactive updates, but it is not exercised by the current verification suite.

3. **Periodic torsions not composed.** The torsion energy term is implemented and its forces verified by numerical differentiation, but it is not included in the default `CompositeModel`. Manual construction is required to include torsion terms.

4. **Dipole and polarisation interactions.** An SCF polarisation solver (Applequist/Thole) is implemented and produces induced dipole moments, but it is not wired into the default evaluation chain. The U_{pol} term in the energy ledger is reserved but currently zero in production evaluations.

5. **PBC not exercised in cluster tests.** Suites G, N, and Q run noble gas clusters and crystal builder tests without periodic boundary conditions. PBC is verified indirectly through the crystal geometry checks (Suite D) and supercell replication (Suite L).

6. **Bonded force-field coverage.** Harmonic bond and angle terms use generic force constants rather than optimised per-molecule parameters from established force fields (AMBER, CHARMM, OPLS). Quantitative molecular thermodynamics requires matched parameterisation.

7. **Local minima in cluster optimisation.** Suite G tests local descent from a single starting geometry (Fibonacci sphere). For $N \geq 4$, the FIRE result is a local minimum, not necessarily the global LJ minimum. Multi-start optimisation is not yet implemented.

8. **Charge equilibration not exercised.** QEq charge equilibration is present in the codebase but not included in the verification suite. Charge arrays (`State::Q`) can be set manually but are not automatically computed from electronic structure.

15.3 Physics Status Registry

The complete physics status at v2.7.1 is summarised in Table 19.

Table 19: Physics status registry at v2.7.1. ACTIVE = verified and evaluated; PARTIAL = implemented but not composed into default chain; DEFERRED = interface intact, contribution zeroed.

Term	State	Note
LJ 12-6 nonbonded	ACTIVE	UFF, Lorentz–Berthelot, quintic switching, 1-2 exclusions
Harmonic bonds	ACTIVE	Generic parameters; composed via CompositeModel
Harmonic angles	ACTIVE	Angle gradient sign bug fixed; force–energy verified
Periodic torsions	PARTIAL	Implemented; not yet composed
Coulomb electrostatics	ACTIVE	Re-enabled with dielectric screening
Dipole interactions	PARTIAL	SCF solver implemented; not in default chain
Induced polarisation	PARTIAL	SCF solver; U_{pol} reserved in ledger
Dielectric screening	ACTIVE	$k_{\text{eff}} = k_e/\varepsilon_r$; 19 solvents verified
PBC / minimum image	ACTIVE	BoxPBC with MIC displacement
FIRE minimisation	ACTIVE	Euler–FIRE deadlock corrected
Velocity Verlet NVE	ACTIVE	Maxwell–Boltzmann init; NVE conservation verified
Langevin NVT	ACTIVE	BAOAB splitting

16 Downstream Workflows Enabled

The verified formation kernel provides a deterministic interface that downstream systems can consume directly. Table 20 summarises the primary workflows that the current kernel enables.

Table 20: Downstream workflows enabled by the formation kernel. Each workflow consumes the generated atomic state without knowledge of how it was produced.

Workflow	**Role of Formation Kernel**
Molecular dynamics	Generate verified starting geometries with correct bond topology, charges, and masses.
DFT / electronic structure	Produce candidate atomic configurations for geometry optimisation or single-point calculations.
Structure exploration	Deterministic candidate generation: given composition and environment, enumerate structurally distinct configurations.
Reaction modelling	Supply physically consistent initial states for reactive pathway calculations.
Crystal prototyping	Composition → lattice → supercell pipeline for materials screening.
Verification baselines	Provide reference structures with known provenance for regression testing of downstream codes.

Each demonstrated system in Sections 11–13 maps to one of these workflows: molecular systems validate topology generation for molecular simulation; crystal systems validate lattice emitters for materials modelling; cluster relaxation validates numerical stability for MD initialisation; dielectric tests validate environment-dependent electrostatics for solution-phase modelling.

17 Future Work

The v2.7.1 milestone establishes a verified kernel baseline. The following directions extend the physical coverage and formation capability of the engine.

17.1 Near-Term Extensions

1. **Bond and angle perturbation scans on polyatomics.** Extend Suite N to H_2O, NH_3, and CH_4 with bonded force fields, verifying that the composite model produces restoring forces toward experimental equilibrium geometries.

2. **PBC crystal stability.** NVE dynamics in periodic supercells with fixed lattice vectors. Validate energy conservation in periodic systems and characterise the relationship between time step and drift.

3. **Torsion composition.** Wire the periodic torsion term into the default `CompositeModel` and verify dihedral rotation barriers for ethane and butane against published AMBER/OPLS values.

4. **Defect perturbation.** Vacancy and interstitial tests in NaCl and Cu supercells. Verify that the engine correctly handles topology changes induced by point defects.

17.2 Medium-Term Development

1. **QEq charge equilibration.** Activate the existing QEq implementation, verify convergence, and validate Coulomb consistency under charge redistribution.

2. **Dipole and polarisation.** Wire the SCF polarisation solver into the default evaluation chain. Verify against known polarisability values for small molecules.

3. **Basin multiplicity.** Multi-start FIRE on Ar_7–Ar_{13} to map the LJ local-minima landscape. Compare against the Cambridge Cluster Database.

4. **Matched force-field parameters.** Implement AMBER or OPLS parameter assignment for common organic functional groups, enabling quantitative comparison with experimental thermodynamic data.

17.3 Long-Term Research Directions

1. **Reactive molecular dynamics.** Bond formation and breaking with energy-gated topology updates, extending the heat-gated reaction control framework from v2.5.3.

2. **Polymorph discovery.** Automated crystal structure search using formation priors, basin mapping, and energy ranking. The goal is to predict stable crystal polymorphs from composition alone.

3. **Autonomous structural exploration.** Coupling the formation engine to a search algorithm that systematically explores configuration space, generating candidate structures and evaluating their stability without human intervention.

4. **Multi-scale integration.** Connecting the atomistic kernel to continuum models for systems where the relevant physics spans multiple length scales.

18 Conclusion

This paper has presented the architecture, energy model, numerical methods, and verification framework of the VSEPR-SIM deterministic atomistic formation engine at version 2.7.1.

The kernel has been verified for:

- Lennard–Jones interactions across 42 UFF elements, with force–energy consistency $< 10^{-3}$ relative error and analytic well depths reproduced to < 0.001 kcal/mol.

- Coulomb electrostatics with exact $1/r$ scaling ($< 10^{-6}$ relative error) and dielectric screening validated across 19 solvents from the CRC Handbook, 104th Edition.

- Crystal geometry for 30 Wyckoff reference structures spanning FCC, BCC, rocksalt, CsCl-type, diamond, and HCP lattice types, all within 3% nearest-neighbour distance tolerance.

- Molecular bond detection for 9 canonical molecules with exact bond counts.

- FIRE minimisation on noble gas clusters (Ar_2–Ar_7), converging to $F_{\mathrm{rms}} < 10^{-5}$ kcal/mol/Å with no deadlock or stagnation.

- NVE energy conservation at $< 3 \times 10^{-11}$ kcal/mol drift over 1000 steps.

- Empirical cross-checks against 25 PubChem bond lengths and 20 NIST spectroscopic constants.

In total, 485 verification checks — 256 in the deep suite and 229 in the phased revalidation — pass without failure or skip. The result is reproducible via the canonical seed `1772952709` and archived verbose output.

The verification process itself produced significant results: four bugs (parser type-map, bonded-pair exclusion, angle gradient sign, FIRE deadlock) were discovered and corrected through systematic verification, none of which would have been detected through normal use. This confirms the central thesis of the project: deterministic formation physics requires deterministic kernels, and deterministic kernels require verification-driven development.

This milestone establishes the first fully verified deterministic kernel baseline for VSEPR-SIM, completing the transition from foundational correctness recovery to a stable platform for convergence tightening, expanded physical coverage, and formation-oriented workflow integration.

Scientific implication. By establishing a deterministic and verified formation kernel, the present work provides a reproducible computational interface between compositional chemistry and downstream atomistic simulation. Such a layer enables systematic exploration of formation behaviour — the generation of atomic configurations from composition and environment — while ensuring that every generated structure is physically consistent, numerically stable, and exactly reproducible. The kernel is not a theoretical proposal; it is a documented, verified, and production-ready computational instrument.
